# 1 ABSTRACT

In the current debate surrounding nanofluids, more experimental studies are required for comparison to clarify much of the ambiguity surrounding the thermal conductivity of nanofluids. In recent years the development of nanofluids has come to a relatively slow crawl due to disagreements in results reported from different testing methods. The following study explores designing and constructing a guarded hot plate (GHP) apparatus. The apparatus was calibrated using deionized water. The GHP was then used to test the ethylene glycol and a Cobalt Oxide nanofluid's thermal conductivity, which was compared to existing reported results and numerical models of nanofluids. Ethylene glycol is a base fluid used for the nanofluids and will be used to establish a baseline.

A finite element analysis(FEA) analysis was performed to validate numerical models of the device and to guide engineering choices of the selection of components; The GHP uses Fourier's law of thermal conduction to extract the sample's thermal conductivity. The GHP uses an embedded system that replicates steady-state conditions. The thermal conductivity is computed using the temperature readings from the two parallel plates and the voltage drop and current measurements across the 120W resistive heat elements embedded in the hot plate. The embedded system uses a PI controller to maintain the cold plate temperature at 20°C through a 154W Peltier element. The Guard heater will maintain parity between the hot plate and the guard heater to ensure heat flux through the sample. The system was designed for a temperature differential of 40°C.

The research has led to the successful measurement of Cobalt Oxide nanofluids And their comparison to similar fluids and numerical models. The research endeavours to address if there is an increase in thermal conductivity using a methodology not frequently employed in the existing literature.

## 2 ACKNOWLEDGEMENTS

### **I wish to thank:**

- My Loving parents, Janet and Francois Snyders, for their continued support of my dreams and aspirations.
- My supervisors, Dr Nemraoui and Dr Ismail, For providing me with technical insight and continued support of my academic endeavours.
- Dr Saleh, For introducing me to the fascinating topic of nanofluids.
- Matthew Schouw, Daniel Barnard and Deen Ebrahim for their assistance and motivation in completing this degree.

The financial assistance of the Cape Peninsula University of Technology towards this research is acknowledged. Opinions expressed in this thesis and the conclusions arrived at are those of the author, and are not necessarily to be attributed to the Cape Peninsula University of Technology.

## GLOSSARY

Acronyms/Abbreviations	Definition/Explanation
AIO	All In One
ASRE	American Society of refrigeration engineer
ASTM	American Society for Testing and Materials
BET	Brunauer–Emmett–Teller
BS	British Standard
CNC	Computer Numerical control
CRM	Chemical Reduction Method
DIN	Deutsches Institut für Normung
FEA	Finite element analysis
GHP	Guarded hot plate
LASiS	Laser Ablation Synthesis in Solution
MOSFET	Metal–oxide–semiconductor field-effect transistor
NBS	National Bureau of Standards
PCB	Printed circuit board
PID	Proportional integral derviative
PTFE	Polytetrafluoroethylene
PWM	Pulse width modulation
THW	Transient hot wire
TPS	Transient plane source

Symbols	
$\dot{Q} =$	Rate of heat conduction
$k =$	Thermal conductivity
$A =$	Area
$k_{eff} =$	Effective thermal conductivity.
$k_p =$	Particle thermal conductivity.
$k_f =$	Fluid thermal conductivity.
$\phi =$	Volume fraction.
$\alpha =$	The ratio of particle to base fluid thermal conductivity.
$\beta =$	$(\alpha - 1) / (\alpha - 2)$ .
$k_{nf} =$	Thermal conductivity of nanofluid.
$k_f =$	Thermal conductivity of the base fluid.
$k_p =$	Thermal conductivity of nanoparticles.
$C_1 =$	Proportional constant ( $18 \times 10^6$ ).
$d_f =$	Diameter of fluid.
$d_{nano} =$	Diameter of the nanoparticle.
$Re =$	Reynolds number.
$Pr =$	Prandtl number.
$k_f =$	Thermal conductivity of the fluid.

$k_p =$	Thermal conductivity of nanoparticles.
$\omega =$	Correction factor.
$T =$	Temperature.
$T_0 =$	Reference temperature (293°K).
$\tau =$	Shear stress.
$\mu =$	Absolute viscosity.
$du =$	Change in velocity.
$dy =$	Change in the distance between surfaces.
$\rho =$	density
$m =$	mass
$V =$	Volume
$\rho_{nf} =$	The density of the nanofluid
$\rho_f =$	The density of the base fluid
$\rho_p =$	The density of the nanoparticle
$R(t) =$	Resistance at a given time.
$R_0 =$	Initial resistance
$\alpha =$	Temperature coefficient of resistance.
$\Delta T =$	Change in temperature.
$\tau =$	Time-dependent constant.
$R =$	Thermal resistance
$\Delta x =$	Thickness

<b>Glossary of terms</b>	
Agglomeration	A clump of multiple particles.
Analogue to digital	An integrated circuit used to convert analogue signals to digital signals.
Attritor	A grinding machine used to reduce the size of particles.
Chemical precursor	A chemical precursor is a chemical used to produce another chemical compound.
Convection	A movement within a fluid caused by density changes due to temperature differentials.
Crystalline	A highly ordered microstructure. A solid material is arranged into a lattice structure.
Density	A measure of the mass per unit volume of a substance.
Dispersants	Dispersants are an additive to a liquid or solid medium to progress the separation of particles.
Heat flux	Heat flux is the measurement of the amount of heat that is transmitted through a material.

<b>Homogeneous</b>	<b>A uniform mixture of two materials.</b>
<b>Least squares method</b>	<b>A numerical method for finding the best fitting curve/line for a data set.</b>
<b>Nanoparticle</b>	<b>A nanoparticle is a particle within the size range of 1 to 100 nm.</b>
<b>Pulse width modulation</b>	<b>A method for reducing the mean power supplied by varying the frequency of the power supplied.</b>
<b>Prandtl number</b>	<b>The ratio of momentum diffusivity and thermal diffusivity.</b>
<b>Reducing agent</b>	<b>A substance that tends to bring about reduction by being oxidized and losing electrons.</b>
<b>Solvent</b>	<b>A substance used to dissolve other materials to form a solution.</b>
<b>Steady state</b>	<b>A constant condition in a physical process. (one in which all variables are controlled.)</b>
<b>Surfactant</b>	<b>A surfactant is an agent that decreases the surface tension between two media.</b>
<b>Suspension</b>	<b>A suspension is a heterogeneous mixture of a fluid that contains solid particles sufficiently large for sedimentation.</b>
<b>Thermal conductivity</b>	<b>The ability of a material to transfer heat.</b>
<b>Transient</b>	<b>A momentary or rapid process.</b>
<b>Viscosity</b>	<b>A measure of a fluid's resistance to flow.</b>
<b>Wheat stone bridge</b>	<b>An electrical circuit used to determine an unknown resistance.</b>
<b>Van Der Waals force</b>	<b>weak, short-range electrostatic attractive forces between uncharged molecules, arising from the interaction of permanent or transient electric dipole moments.</b>
<b>Zeta potential</b>	<b>The electrical potential of the shear plane.</b>

# 1 CHAPTER ONE: Introduction

## 1.1 Problem statement

Many problems impede nanofluids' advancement, some of which are not directly linked to nanofluids. Suider *et al.* (2011) attribute these factors to the poor characterisation of suspensions of nanoparticles, the lack of agreement of results between researchers and a lack of understanding of the mechanisms behind the changing of properties between nanoparticles and the base fluid. Considering the lack of agreement with the reported increase in the thermal conductivity of nanofluids, there has been speculation about the accuracy of the results.

In this investigation, the basic concept of Fourier's Law of conduction will govern the thermodynamic analysis used for the nanofluids. Fourier's Law states that the rate of heat conduction is directly proportional to the temperature difference across a given area but inversely proportional to the thickness of the plane upon which the heat is conducted (Yunus & Afshin, 2015). The Law is represented by Equation (5.1); the coefficient of proportionality denoted as "k" is known as thermal conductivity. Yunus and Afshin (2015) define *thermal conductivity* as the measurement of the ability of a material to conduct heat.

$$\dot{Q} = -kA \frac{\Delta T}{\Delta x} \tag{5.1}$$

Where:

- $\dot{Q}$ = Rate of heat conduction
- k= Thermal conductivity
- A= Area
- $\Delta T$ = Change in temperature
- $\Delta x$ = Thickness

A steady-state system is one in which the variables remain constant when analysing heat conduction as time progresses. The one-dimensional steady-state (Equation (5.1)) forms the basis for the analysis of thermal systems in the

thermal analysis industry. A guarded hot plate apparatus (GHP) measures nanofluids' thermal conductivity. The GHP apparatus was developed simultaneously in the 19<sup>th</sup> century in America and Germany; however, the initial design was used to measure insulating materials' thermal conductivity (Thermtest Inc., 2015b). The GHP apparatus uses steady-state conditions and Fourier's Law of thermal conduction in its operation and is still in use to this day. A schematic of the original two specimen set up is presented in Figure 1.2.

**Figure 1.1: A schematic diagram illustrating the original design of the GHP apparatus (Thermtest Inc., 2015b)**

The GHP design was modified by Channel and Powel in 1956 to measure the thermal conductivity of water but was further modified to measure the thermal conductivity of nanofluids by Wang and Xu in 1999 (Wang & Xu, 1999). The schematic of the apparatus used by Wang and Xu can be seen in **Figure 1.2**.

Figure 1.2: Guarded hot plate apparatus schematic diagram (Wang & Xu, 1999)

The fluid sample was placed between two parallel plates constructed of round copper. The copper plates are separated by a set of glass spacer rings which rest on the cold plate below. The fluid level is slightly above the base of the bottom of the upper plate; any excess fluid is forced out the side of the glass spacer rings, ensuring no air is in the system, which may skew the results and render them invalid. To control the temperature around the system, aluminium cells with heating elements are placed around the testing chamber and heated to match the surface temperature of the hot plate. The heat flux in the direction of the cold plate eliminates the convection and radiation losses from the upper copper plate. The control of the heat flux replicates the steady-state conditions (Wang & Xu, 1999).

Various factors have been reported to influence the thermal conductivity of nanofluids. According to a review on thermophysical properties of nanofluids and heat transfer applications by Gupta *et al.* (2017), the factors include the particle size, the particle shape, the material of the solid particle, the base fluid, the temperature, additives (specifically surfactants), the pH value of the nanofluid and clustering (Gupta *et al.*, 2017). Two primary mechanisms have been identified for the increased thermal conductivity, the Brownian motion of the nanoparticles and the interfacial layer. Kole and Dey (2011) have noted in their experimental study that the effects of Brownian motion are only prevalent for temperatures greater than 30 °C (Kole & Dey, 2011). Gupta *et al.* (2017) stated that the interfacial layer acts as a ‘thermal bridge’ between the solid

particles and base fluid. However, these factors have been overlooked during the test phase of the thermophysical properties of nanofluids.

## **1.2 Aims and objectives**

The primary aims of this project are to design, fabricate and evaluate a GHP test apparatus to test nanofluid thermal conductivity. The following key objectives need to be implemented within the GHP apparatus.

- Design, computer-aided simulation

The modelling of the apparatus during the design phase will provide insight into the performance of the selected components. This concept will evaluate the thermal conductivity of nanofluids in a controlled environment.

- Construction of a prototype

The prototype will be constructed to verify the simulated models.

- Testing of the prototype

The readings from the prototype will be compared to the published results of two controls: water and ethylene glycol. These results will prove whether the prototype is providing accurate and trustworthy results.

- Testing of a nanofluid

A nanofluid will be tested and compared to existing reported results and predictive numerical models.

## **1.3 Constraints**

The prototype will only measure thermal conductivity of nanofluids. Only a cobalt oxide nanofluid will be used for comparison.

## 1.4 Methodology

- *Phase 1: Literature review*

A literature review will provide relevant information on the nanofluids and the design of the apparatus to evaluate the thermal conductivity. The literature review will be presented in Chapter 2.

- *Phase 2: Design of the modified guarded hot plate apparatus*

The apparatus will be designed using Solidworks™ and optimised using Abaqus to ensure heat is evenly distributed throughout the system, thereby enabling a numerical value to compare the prototype. This phase is detailed in Chapter 3.

- *Phase 3: Construct and commission a modified guarded hot plate apparatus prototype*

The apparatus will then be constructed, commissioned using water, and used to record nanofluids' thermal conductivity, detailed in Chapter 4.

- *Phase 4: Analysis of results*

The results will then be analysed and compared to other publications of a similar nature and will also be compared to the predicted results of various numerical models that have been proposed over the years. This phase will be further detailed in Chapter 5.

## 2 CHAPTER TWO: Literature review

Stephen Choi first coined the term *nanofluid* in the 90s to describe the suspension of particles (<100 μm) within a base fluid. The idea of suspending a solid medium within a fluid is not new. Maxwell first theorised the concept in the 1800s; however, the Maxwell model is confined to micrometre and millimetre-sized particles (Choi & Eastman, 1995). It is worth noting that the Maxwell equation severely underpredicts the thermal conductivities of nanofluids at higher temperature differentials (Kole & Dey, 2011). Nanofluids are a class of fluids of their own, despite their similarity to slurries. The Maxwell equation established the foundation upon which the effective thermal conductivity of nanofluids was established, as given in Equation (2.1).

$$k_{eff} = \frac{k_p + 2k_f + 2(k_p - k_f)\phi}{k_p + 2k_f - (k_p - k_f)\phi} k_f \quad (2.1)$$

Where:

$k_{eff}$	=	Effective thermal conductivity
$k_p$	=	Particle thermal conductivity
$k_f$	=	Fluid thermal conductivity
$\phi$	=	Volume fraction

The discovery of nanofluids yielded new possibilities for heat transfer. In the heat transfer Equation (1.1), there are three ways of increasing heat conduction: increasing the area (A) of the contact area; increasing the temperature differential ( $\Delta T$ ); or increasing the heat transfer coefficient (k). The system may be constrained by space, making it unfeasible to manipulate the area. Temperature differences could be limited by process or material. The last parameter that can be manipulated is thermal conductivity. The increased heat transfer coefficient can be achieved by utilising more efficient methods or improving the heat transfer medium. In the case of fluids, nanoparticles are used (Saidur, Leong & Mohammad, 2011).

The properties of nanofluids are influenced by five parameters: particle characteristics, thermo-fluids, heat transfer, colloid, lubrication, viscosity, viscosity index, friction coefficient, wear rate and extreme pressure. The properties of a particle are its size, shape, BET (surface area analysis) and crystalline phase. Thermo fluid properties include temperature, viscosity, density, specific heat and enthalpy. Heat transfer properties include thermal conductivity, heat capacity, Prandtl number and pressure drop. Colloid properties are influenced the by suspension stability, zeta potential and pH value (Devendiran & Amirtham, 2016).

A review was undertaken by Saidur *et al.* (2011) who noted multiple uses of nanofluids. As of the article's publication, the following uses have been listed: cooling of electronics, solar water heating and thermal storage. These are just a few applications; however, renewable energy is of particular interest. It was reported in the study that the nanofluids increase the absorption of incident radiation by more than nine times when compared to plain water (although it was suggested that better-designed solar absorption systems might be able to outperform nanofluid-based solar collectors in certain conditions). The addition of nanofluids could significantly increase the performance; however, the next problem is the challenges of nanofluids (Saidur, Leong & Mohammad, 2011). These challenges include the long-term stability of nanoparticle dispersion, increased pressure drop, pumping power requirements, nanofluid thermal performance in turbulent flow and fully developed flow regions, higher viscosity, lower specific heat, thermal conductivity, high production cost, and the difficulties inherent with the production processes (Devendiran & Amirtham, 2016).

According to Saidur *et al.* (2011), research into nanofluids is hindered by a lack of consistency of results obtained by researchers, poor characterisation of the suspensions and a lack of theoretical understanding of the mechanisms responsible for changes in properties. The nanoparticle's stability inside the fluid is one of a nanofluid's fundamental requirements. The preparation of stable nanofluids through a homogenous suspension is a technical challenge because the nanoparticles tend to aggregate due to the strong van der Waal interactions. Physical or chemical treatments can be implemented to obtain stability. A direct correlation was noted between stability and thermal conductivity enhancement,

although with time, the stability of nanofluids changed, and the nanoparticles tended to settle. Thermal conductivity is highest when the nanofluid is freshly prepared, and there is a noticeable performance degradation over time. A challenge presented by nanofluids is increased pressure drop associated with the increasing viscosity over the base fluids' viscosity and lower specific heat capacity (Saidur, Leong & Mohammad, 2011).

## **2.1 Synthesis and preparation**

Nanofluids' preparation phase requires a stable suspension, low agglomeration of nanoparticles and no chemical change to the fluids. The addition of surfactants or any agent that facilitates a nanoparticle's suspension will affect the nanofluid's thermophysical properties (Devendiran & Amirtham, 2016). Xuan and Li (2002) suggest three methods for stabilising the suspensions: surface activators and dispersants, changing the pH value of suspensions and ultrasonic vibration. These methods can change the surface properties of the suspended particles and can be used to suppress the tendency to agglomerate, increasing the stability of the suspension.

There are two methodologies for synthesising nanofluids: the one-step and the two-step method. It should be noted that the preparation methodology affects the stability of nanofluids. The synthesis of nanofluids has challenges such as thermal stability, dispersibility and chemical compatibility (Das *et al.*, 2007). "Thermal stability is defined as the ability of a fluid to resist breaking down under heat stress" (Spurlin.com). Dispersion stability refers to the ability of the nanoparticle to remain in a uniform distribution within the base fluid, not to be confused with solubility (Ha, Weitzmann & Beck, 2013). Lastly, chemical compatibility measures the stability of the nanoparticles within the solvent.

### **2.1.1 Two-step methodology**

The two-step methodology involves dispersing a nanopowder into a solvent in two separate phases. Most nanofluids containing oxide nanoparticles and carbon nanotubes reported in academic studies are produced via this methodology (Das *et al.*, 2007). The nanopowders are obtained via chemical

reduction or mechanical crushing. Once the nanopowder is placed into the base fluid/solvent, it is magnetically stirred and then sonicated at various frequencies depending on the combination of nanopowder and base fluid (Devendiran & Amirtham, 2016). Nanofluids produced using the two-step method have been known to agglomerate before being dispersed. The lack of dispersion reduces the effective thermal conductivity of the nanofluid, and the agglomerated clusters tend to settle, further reducing the stability of the nanofluid.

There are two primary methods of fabricating nanoparticles, bottom-up and top-down methods. The top-down method involves breaking down bulk materials to the desired size. The bottom-up method involves constructing the nanoparticles from constituent atoms (Critchley, 2019).

Top-down approaches can produce copious quantities of nanopowders; however, this approach has no control over the shape and size distribution of the particles produced. The first variation of a top-down approach is that of mechanical attrition. As the name suggests, mechanical attrition involves the milling, shearing, cleaving or wearing down bulk material to the nano-size range (20nm-100nm) (Critchley, 2019). The attrition of materials is the backbone of many industries, including but not limited to the mineral industry, ceramics and powder metallurgy industries. Mechanical attrition is referred to as mechanical milling or a tumbler ball mill. The working principle behind mechanical milling is the transference of kinetic energy from the mechanical balls (usually tungsten carbide or hardened steel) to the material being broken down. The kinetic energy is a function of their mass and velocity; however, too dense a packing of these metallic balls reduces the free path of the ball's motion, thereby reducing the effect of collisions. The first mechanical milling method used is the high-energy ball mill, which John Benjamin first developed in the 1960s at the International Nickle Company. The primary objective of milling is particle size reduction, mixing and blending, particle shape changes and the synthesis of nanocomposites. The typical setup consists of a hollow cylinder rotating around its axis with metallic balls. The balls impact the bulk material as the mill rotates, breaking the material down into a fine powder. It should be noted that the tumbler ball mill is operated as close to the critical speed as possible to maximise the kinetic energy transfer to the balls. Speeds greater than the critical speed will cause the centrifugal forces to overcome the centripetal forces,

forcing the metallic balls to the outside of the shell and pinning them there. The attritor is a modification of the mechanical. Szegvari developed the attritor in 1922. This mill consists of a vertical cylindrical shell with a shaft running down the centre. On the shaft, there are horizontal arms that stir the metal balls. The rotation of the vertical shaft causes differential movement between the balls and the material being broken down. This method provides a more significant surface contact than the latter (Yadav, Yadav & Singh, 2012).

The chemical reduction method (CRM) is the most common two-step methodology. CRM is a simplistic, non-time-consuming methodology for producing nanoparticles. CRMs can be categorised into two subgroups: co-reduction and successive reduction. Co-reduction involves two different metal salts, and the second method is the successive reduction of two metal salts. CRM is considered a bottom-up method of producing nanoparticles as it relies heavily on three stages: organic synthesis, self-assembly and colloidal aggregation. It was noted by Manikim *et al.* that CRMs could produce finer nanoparticles than mechanical means. CRMs are not without their disadvantages, however, the most important of which is that the chemicals used in this method are harmful to the environment, particularly when scaled up for mass production. The chemical reduction method comprises three items: a precursor, a reducing agent and a stabiliser or protective agent. A catalyst may also be added to speed up the reaction rate (Manikam, Cheong & Razak, 2011). A chemical precursor is a chemical that is changed into another compound during a chemical reaction. Reducing agents are defined as compounds or elements that lose an electron during the chemical reaction (Purdue University, 2004), and a stabiliser is an agent that hinders further reactions and prevents degradation of the nanoparticles into clusters (Hawkins, 2014). The surfactant type and reducing agent influence particle size; more potent reducing agents generate narrower particles. These narrower particles avoid agglomeration better than others (Manikam, Cheong & Razak, 2011).

### **2.1.2 One-step methodology**

As the name suggests, the one-step methodology combines the manufacturing and dispersion of a nanoparticle into a base fluid in one process (Das *et al.*,

2007). Nanofluids produced through this method have proven to be more stable than those produced through the latter.

LASiS is considered a one-step methodology and is free of the disadvantages presented by CRMs. In LASiS, nanoparticles are produced during the condensation of a plasma plume formed by the laser ablation of a metal specimen suspended within a liquid. Amendola and Meneghetti (2009) note that the process had been used successfully to create nanoparticles of gold, silver, platinum, copper and other materials in various solvents. It was pointed out that the poor control of NMNp size and size distribution can be controlled by laser irradiation, exploitation of plasmon absorption or interband transitions. Despite these perceived shortcomings, the most significant advantage is that NMNps can be obtained stable within solvents without stabilising agents (Amendola & Meneghetti, 2009).

The basic setup of the LASiS process consists of a pulsed laser, a set of focusing optics and a container with a metal plate suspended within a liquid. The metal, placed in the focal point of the laser, can be seen in **Figure 2.1**. The most critical parameters for the LASiS process are the time duration, wavelength and fluence of the laser pulses (Amendola & Meneghetti, 2009).

**Figure 2.1 Basic setup of the laser ablation process (Amendola & Meneghetti, 2009)**

### 2.1.3 Preparation

The stability of the fluid affects the performance of nanofluids. Agglomeration is a challenge faced by nanofluids. Nanofluids naturally tend to agglomerate, allowing the particle clusters to be overcome by gravitational effects. The deterioration of nanofluids manifests as an increase in unwanted thermophysical properties of nanofluids, such as viscosity. The increase of clustering within the fluid may also reduce the thermal conductivity of the nanofluid. To circumvent agglomeration in nanofluids, they are subjected to sonication to separate them. Sonication is not the only means of reducing the effects of agglomeration, as there are other alternatives such as magnetic stirring, surface charge and the addition of surfactants. There is a correlation between sonication time and nanofluid stability. Ultrasonication can be categorised into two categories: direct and indirect sonication. Direct sonication involves direct contact between the horn of the ultrasonic homogeniser and the sample. Indirect sonication involves an intermediary medium between the sample and the ultrasonic head. The most common indirect sonication method is the ultrasonic bath. The primary mechanism behind sonication is cavitation. The cavitation allows for nanoparticle dispersion and may even lead to smaller particles being formulated in the nanofluid.

It should be noted that direct sonication provides a more direct and focused ultrasonic effect on the fluid, whilst indirect ultrasonication provides a low-intensity and broad-spread effect. Two parameters of ultrasonication affect nanofluid the most: the power of sonication and the duration of the sonication (Asadi *et al.*, 2019). The sonication time and power positively affect the thermal conductivity of nanofluids. The thermal conductivity increases with sonication time until a critical point, after which there is a decrease in thermal conductivity. The typical sonication time for a nanofluid is approximately two hours at 500 W (Haddad *et al.*, 2014).

The addition of surfactants is another means of increasing the stability of nanofluids. The surfactants have a positive effect on stability but a negative effect on thermal conductivity. The surfactant modifies the surface properties of the particle. The selection of surfactants is crucial for the stability of nanofluids. Surfactants fall into three categories: cationic, anionic or non-ionic. The addition of surfactants affects the pH value of the nanofluid (Ilyas, Pendyala & Marneni, 2014).

## 2.2 Properties

### 2.2.1 Thermal conductivity

Thermal conductivity is the most crucial property responsible for the enhancement of the thermal performance of nanofluids (Devendiran & Amirtham, 2016). According to Cengal & Afshin (2015), thermal conductivity is "the rate of heat transfer through a unit thickness of the material per unit area per unit temperature difference" (Yunus & Afshin, 2015:18). The definition can be expressed mathematically in Equation (5.1). Devendiran and Amirtham (2016) note that the experimental results proved the thermal conductivity increased, and they disagreed with the numerical models for nanofluids. Numerical models often underpredict the thermal conductivity of nanofluids. Khedar *et al.* (2012) tested the effect of CuO nanoparticles in water and monoethylene glycol, and determined that for nanofluids comprising of water and CuO nanoparticles, there was a maximum increase of 21.26% in thermal conductivity over that of water. For monoethylene glycol nanofluids, there was a maximum increase of 32.25%, and both results were taken at a 7.5% volume fraction (Khedkar, Sonawane & Wasewar, 2012). Hu, Fei and Chen tested the performance of AlN nanoparticles in ethanol, recording a 20% increase in thermal conductivity over that of the base fluid with a 4% volume fraction (Hu, Fei & Chen, 2008). Saidur, Leong and Mohammad observed a lack of explicit agreement between reported results (Saidur, Leong & Mohammad, 2011).

Apart from experimental studies, various mathematical models have been proposed to predict the thermal conductivity of nanofluids. The Maxwell model has already been discussed in Chapter 1 (5.1). The Jeffery model, as seen in Equation (2.2) was proposed by D. Jeffery in 1973 to approximate spherical particles suspended in a base fluid. The model assumes a homogeneous suspension of spherical particles within the fluid (Jeffrey, 1973).

$$\frac{k_e}{k_f} = 1 + 3\beta\phi + \phi^2(3\beta^2 + \frac{3\beta^2}{4} + \frac{9\beta^3}{16} \frac{\alpha + 2}{2\alpha + 3} + \frac{3\beta^4}{2^6} \dots)$$

(2.2)

Where:

- $k_e$  = Effective thermal conductivity
- $k_f$  = Base fluid thermal conductivity
- $\alpha$  = Ratio of particle-to-base fluid thermal conductivity
- $\beta$  =  $(\alpha-1)/(\alpha-2)$
- $\phi$  = Volume fraction

In 2004, Yu and Choi modified the Maxwell model to accommodate nanofluids. The model explicitly considers the collisions of the molecules, thermal diffusion, volume fraction, particle size and temperature. This modification was made after an initial model created by Jang and Choi in 2003; the model specifically considers the nanolayer effect. It should be noted that the model was restricted to water-based nanofluid in a rectangular cavity. The nanoparticles used were 6 nm copper and 2 nm diamond particles with a 0.5% to 2% volume fraction. In the study, they exclusively calculated the theoretical results of the nanofluids and concluded that there was an increase in thermal conductivity according to the model (Yu & Choi, 2004).

$$k_{nf} = k_f(1 - \phi) + k_p\phi + 3C_1 \frac{d_f}{d_{nano}} k_f Re^2 d_{nano} Pr \phi$$

(2.3)

Where:

- $k_{nf}$  = Thermal conductivity of nanofluid
- $k_f$  = Thermal conductivity of the base fluid

$\phi$	=	Volume fraction
$k_p$	=	Thermal conductivity of nanoparticles
$C_1$	=	Proportional constant ( $18 \times 10^6$ )
$d_f$	=	Diameter of fluid
$d_{nano}$	=	Diameter of the nanoparticle
Re	=	Reynolds number
Pr	=	Prandtl number

A recent numerical model, developed by Garoosi in 2020, was based on various published experimental studies of metal oxide nanofluid. It compensates for volume fractions ranging from 0% to 12% and particle sizes ranging from 5  $\mu\text{m}$  to 10 nm. It was found that older models, such as the Maxwell-Garnet model, underpredicted the thermal conductivity and were far too conservative. According to Garoosi, existing models show agreement between experimental and theoretical results but are limited to spherical nanoparticles. The model proposed in Equation (2.4) agreed with a larger pool of published data than its predecessors and is one of the most recent models to achieve this agreement. The proposed model was derived using the least-squares method; it has a 4.7% standard deviation from the 458 experimental data sets (Garoosi, 2020).

$$\frac{k_{nf}}{k_f} = \frac{k_p + 2k_f + 2(k_p - k_f)\phi}{k_p + 2k_f - (k_p - k_f)\omega\phi} + 3.762\left(\frac{T}{T_0}\right)^{8.661}\left(\frac{d_p}{d_f}\right)^{-0.4351}\left(\frac{k_p}{k_f}\right)^{0.08235}\phi^{0.64}e^{(-5.742\phi)}$$

(2.4)

Where:

$k_{nf}$	=	Thermal conductivity of nanofluid
$k_f$	=	Thermal conductivity of the fluid
$k_p$	=	Thermal conductivity of nanoparticles
$\omega$	=	Correction factor
$\phi$	=	Volume fraction
$T$	=	Temperature

$T_0 =$	Reference temperature (293 °K)
$d_p =$	Diameter of the nanoparticle
$d_f =$	Diameter of the base fluid

### 2.2.2 Viscosity

Viscosity is best described as a fluid's internal resistance to motion/flow (Cengel & Cimbala, 2013). Mathematically the viscosity of a Newtonian fluid can be described by Equation (2.5) (Upadhyay, 2017). Equation (2.5) is known as Newton's Law of viscosity as follows:

$$\tau = \mu \frac{du}{dy} \tag{2.5}$$

Where:

$\tau =$	Shear stress
$\mu =$	Absolute viscosity
$du =$	Change in velocity
$dy =$	Change in the distance between surfaces

The viscosity of nanofluids relies on particle size, particle shape, particle size distribution, volume concentration, aggregation, temperature, pH value and dispersion method (Chandra & Sayantan, 2014). The base fluid on its own will usually exhibit Newtonian behaviour, but the addition of nanoparticles sometimes results in the fluid exhibiting non-Newtonian behaviour (Liu *et al.*, 2020). Nanofluids with even distributions of nanoparticles and a volume fraction less than or equal to 0.6% would display Newtonian behaviour. However, fluids with a volume fraction greater than 0.6% will begin to exhibit shear thinning and, as such, can no longer be considered Newtonian fluid (Li *et al.*, 2015). Multi-walled carbon nanotubes (MWCNT) in liquid paraffin are a recent development in nanomaterials. MWCNT nanofluids exhibit non-Newtonian behaviour, and the greater the volume fraction/temperature differential, the more significant the

deviation from Newtonian behaviour (Liu *et al.*, 2020). Fe-Si nanoparticles in water showed an almost sinusoidal curve of viscosity compared to concentration; in the study, the maximum viscosity was found at a volume fraction of 1.0% (Huminić, Huminić & Fleacă, 2020). There is an exponential relationship between the volume fraction and viscosity (Bao *et al.*, 2021).

### 2.2.3 Density

Density, traditionally defined as the mass per unit volume, is typically expressed by the following equation (Douglas *et al.*, 2005):

$$\rho = \frac{m}{V}$$

**(2.6)**

Where:

$\rho$ = Density  
 $m$ = Mass  
 $V$ = Volume

However, the formula does not consider that nanofluids contain both solids and liquids; therefore, the equation is insufficient to approximate the density of nanofluids. Equation **(2.7)** provides the density of the base fluid and the particle. The density is based on the volume fraction of nanoparticles added to the base fluid (Garoosi, 2020).

$$\rho_{nf} = (1 - \phi)\rho_f + \phi\rho_p$$

**(2.7)**

Where:

$\rho_{nf}$ = Density of the nanofluid  
 $\rho_f$ = Density of the base fluid  
 $\rho_p$ = Density of the nanoparticle  
 $\phi$ = Volume fraction

#### 2.2.4 Characterisation

There are multiple ways to evaluate the thermal conductivity of nanofluids, such as the transient hot wire (THW), hot disk technique, temperature oscillation technique and the guarded hot plate apparatus. Much of the disagreement of results stems from the various testing methodologies employed by various researchers. Zagabathuni, Ghosh and Pabi compared the results obtained from the laser flash method to those of the THW method and found that the laser flash method obtained results one order of magnitude lower than the THW methodology. The measurement of the thermal conductivity of nanofluids falls into one of two distinct categories: steady-state or transient. The steady-state was discussed in section 1.1; the transient state is one in which the heat transfer is rapid (Zagabathuni, Ghosh & Pabi, 2016).

A typical modern THW setup consists of the transient hot-wire apparatus, an analogue-to-digital converter and a computer or data logger (Loong & Salleh, 2017). The analogue-to-digital converter would not be necessary if the data logger is used. A schematic view is presented in **Figure 2.2**. The THW apparatus consists of a platinum hot wire with a diameter ranging from 12.7  $\mu\text{m}$  to 50.8  $\mu\text{m}$  (depending on commercial availability), a pressure cell/container and a wheat stone bridge. In more recent iterations of the THW apparatus, the platinum wire is coated in Teflon to circumvent the electrically conductive nature of metallic nanoparticles present in a nanofluid. As the name suggests, this method falls into the category of transient methods, as the heating and data collection takes place at a rapid pace. This method relies on Fourier's one-dimensional transient heat conduction in the cylindrical bodies' equation. The heat is applied via a platinum wire that passes through the core of the apparatus. The platinum wire is connected to a wheat stone bridge. The power supplied to the platinum wire is monitored and recorded, and the change in resistance of the platinum wire is monitored and used to calculate the thermal conductivity of the fluid sample. **Figure 2.2** displays the typical test setup of the THW.

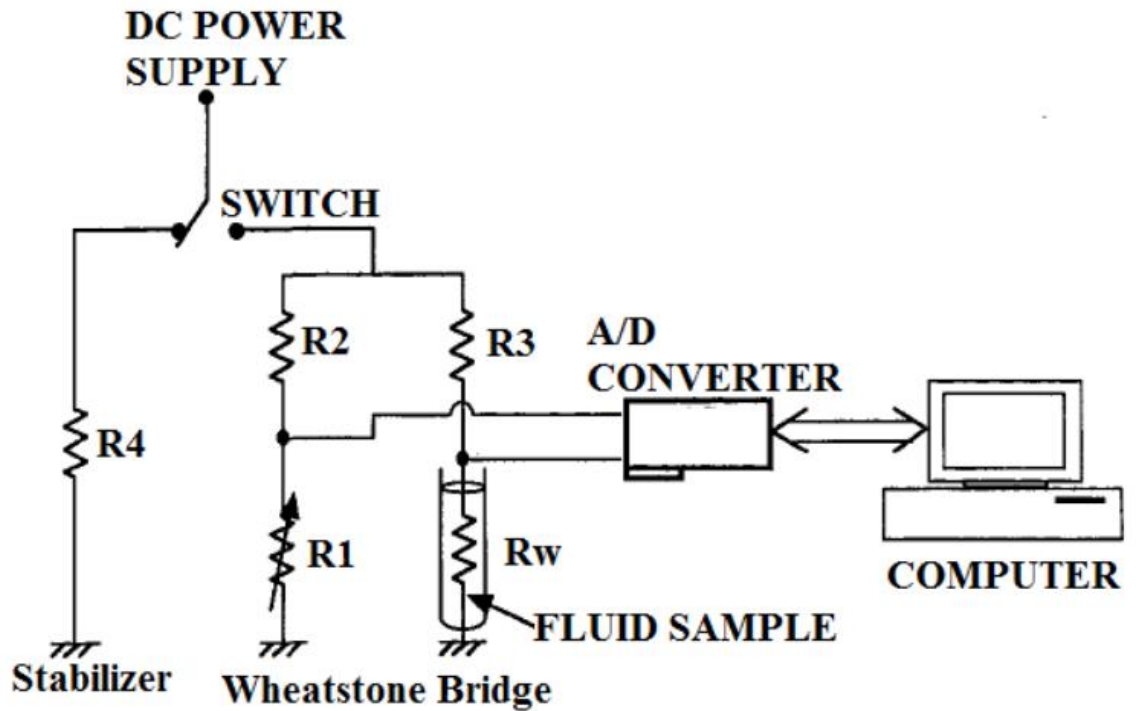

Figure 2.2: Schematic overview of a computerised THW setup (Choi, Li & Eastman, 1999)

Beyond the wheat stone bridge and platinum wire, the setup consists of a hot wire cell, whose sole purpose is to contain the fluid and to provide the relevant tension on the platinum wire.

The transient hot disk is commonly referred to as a transient plane source, thermal constant analyser or Gustafsson probe technique. The typical setup contains the Gustafsson probe, constant temperature bath, material sample and thermometer (Loong & Salleh, 2017). In conjunction with those mentioned earlier, it is used by a thermal analyser to determine the thermal conductivity of a test sample. The transient plane source (TPS) operates on a principle similar to that of the transient hot wire in which the heat source is also the sensor. The change in resistance is measured and used to calculate the thermal conductivity of the fluid (Buonomo *et al.*, 2014). The plane source is typically made of insulated copper or nickel of a double spiral construction, as seen in **Figure 2.3**. The probe itself can be shaped as required to fit the test sample. Custom TPS probes are made of a thin film of copper or nickel and then insulated with Kapton tape (Hu *et al.*, 2008). The working principle is like that of the THW apparatus, but the governing equation deviates from Fourier's Law of heat conduction in cylinders to that of Fourier's Law of heat conduction, as seen in Section (5.1).

The working principle of the TPS probe is that the voltage change across the element is recorded while a direct current pulse heats the element; the pulse is short enough so that the element is considered to be infinite or semi-infinite throughout the transient recording. By doing this, the outer boundaries of the test sample can be negated, and it can be assumed that no external factors are acting on the system other than the controlled variables. The governing equation for a TPS probe is shown in Equation **(2.8)** (Gustafsson, 1991):

$$R(t) = R_0(1 + \alpha \overline{\Delta T(\tau)})$$

**(2.8)**

Where:

$R(t)$	=	Resistance at a given time
$R_0$	=	Initial resistance
$\alpha$	=	Temperature coefficient of resistance
$\Delta T$	=	Change in temperature
$\tau$	=	Time-dependent constant

Equation (2.8) is then substituted into Fourier's Law to calculate the thermal conductivity of a sample. The TPS system has gained market acceptance as a standard in many industries for the measurement of thermal conductivities, as evidenced by systems such as the TPS 2500 S. This model of apparatus has been used by Buonomo *et al.* (2014) and a self-manufactured variant was used by P. Hu *et al.* in their study of AlN-ethanol nanofluids (Hu, Fei & Chen, 2008; Buonomo *et al.*, 2014).

**Figure 2.3: Close up of hot disk design (Gustafsson, 1991)**

The TPS system is capable of measuring between 0.5 K to 2 K, and the sample is open to the atmosphere (Hu, Fei & Chen, 2008). Furthermore, the TPS system is suitable for measuring various materials, encompassing solids and fluids. Commercial models can detect thermal conductivities in the range of 0.005 W/m.K to 500 W/m.K with an uncertainty of 5% (Buonomo *et al.*, 2014). The TPS cannot measure the thermal conductivities of a fluid that undergoes the boiling process, but it does notify the end-user of the presence of natural convection that may skew the results (Loong & Salleh, 2017).

The temperature oscillation technique set-up consists of a cylindrical tube, two Peltier modules placed in series with each other at opposite ends, two end plates that act as heat spreaders and two heat exchangers to dissipate the heat generated by the thermoelectric coolers. The Peltiers are placed in series for a constant current across both Peltier modules, allowing for parity in the temperatures of the two units. The end plates seal the cylinder so the tested fluid cannot leak (Phelan, 2004). The working principle of such a device is based on the transient heat transfer equation. The amplitude attenuation, the phase shift and the amplitude of thermal diffusivity are measured, and the thermal conductivity can be calculated. One of the advantages of this method is its

similarity to that of the  $3\omega$  method; it was relatively simple in comparison to other measurement methods (Badarlis *et al.*, 2020). Czarnetzki and Roetzel (1995) also contend that the method combines the advantages of steady-state measurement with the ability to measure properties that describe non-steady-state conditions (Czarnetzki & Roetzel, 1995). Concerning disadvantages, the lack of literature available was the most likely reason for the lack of adoption amongst many research groups. There is no guidance for the configuration of the experimental setup and what amplitudes and temperature frequency to use (Bhattacharya *et al.*, 2006). The final disadvantage is that the relatively low-temperature ranges that were measured are only within 2.5 °C (Czarnetzki & Roetzel, 1995).

The guarded hot plate apparatus, initially developed in the early 1900s, was based on Lee's disk method (Thermtest Inc., 2015a). The Lee's disk method consisted of a steam chamber, a cast iron upper disk, a slab of a specimen, a cast-iron lower disk and a series of thermometers. The working principle of such an apparatus was that steam was generated, which flowed into the steam chamber. This would in turn heat the upper cast iron disk in direct contact with the specimen slab. Once the system has reached a steady-state, the steam supply and upper cast iron disk is removed whilst the specimen slab and lower cast iron disk remain. The lower disk is then heated to 10 degrees above the steady-state temperature, and readings are then taken every 5 minutes till the lower disk has cooled. Based on these readings, it would be possible to calculate the thermal conductivity of the specimen. A 3D rendering of the setup can be seen in **Figure 2.4**; it should be noted that the steam chamber is in grey, the upper and lower disks are in yellow, and the specimen is in red. The upper and lower disks are of a known mass (Alam *et al.*, 2012).

**Figure 2.4: 3D rendering of Lee's disk method (Thermtest INSTRUMENTS, n.d.)**

In the early 1900s, the guarded hot plate apparatus was developed concurrently in both the United States and Germany. In the United States, the American Society of Refrigeration Engineers (ASRE) requested the National Bureau of Standards (NBS) to develop a means of testing insulation materials. This request is what set the development of the GHP in motion. At the same time as the request from the ASRE, Richard Poensgen of Germany was developing a similar device for the same reason: there has been no standard method of precisely measuring the heat transmission in insulating materials. The two constructed devices had similar experimental setups and operated on the same working principle. Poensgen's device was released first in 1910, and two years later, in 1912, the NBS machine was released. Since then, the GHP apparatus has been an industry standard across fields such as refrigeration and insulation (Thermtest Inc., 2015b).

Two norms govern the GHP apparatus: ASTM C177 and ISO 8302 (Linseis Inc., n.d.). According to Challoner and Powell (1956), they designed a completely enclosed GHP for the explicit purpose of testing liquids, a cross-section of which is presented in **Figure 2.5**. Their device was similar in construction to that of the NBS in that it consisted of the typical cold plate, hot plate and guard heater. This arrangement is typical of GHP setups and typically contains a thermocouple on the respective elements of the setup. In Challoner and Powell's setup, the heat was supplied via resistive heating elements in the guard and hot plate, whilst

the cold plate was kept cool via a water cooling loop that maintained the temperature at  $\pm 0.01$  °C (Challoner & Powell, 1956).

**Figure 2.5: GHP apparatus setup (Challoner & Powell, 1956)**

The basic working principle of a GHP setup is based on Fourier's Law of conduction which was briefly touched on in section 1.1. As previously stated, the typical setup for all GHP setups consists of a guard to prevent heat losses from the hot plate; this is achieved by having a guard temperature that matches that of the hot plate, a hot plate that provides the source of heat to the sample and a cold plate that removes the heat from the sample. Across the sample, a temperature difference will need to be measured, along with the power supplied.

There are two possible configurations for a GHP, the one-plate method and the two-plate method. In the one-plate method, the heat flows in a single direction, and in the two-plate method, the heat flows in two directions. These configurations are illustrated in **Figure 2.6**.

**Figure 2.6: GHP configurations (Linseis Inc., n.d.)**

In 1982 Smith, Hust and VanPoolen (1982) obtained a commercial GHP apparatus from the Langley Research Centre. The group working for the NBS found through experimental means that the device had uncertainty of measurements of glass fibre board of  $\pm 2\%$  at ambient temperatures and  $\pm 5\%$  at sub-ambient temperatures. These results were obtained using the supplied water-cooling loop and then via a modified LN2 loop. The results were deemed out of spec, and the authors noted that this was not representative of all machines supplied by the Langley Research Centre; furthermore, the apparatus was designed to comply with the ASTM C-177 standards. The device was a two-specimen setup consisting of two cold plates, a main heater, an inner guard heater, an outer guard heater, auxiliary cooling plates and an environmental chamber. Altogether, the cold, hot and guards make up the stack. As per **Figure 2.7**, it can be seen that the specimens are placed on either side of the main heater via glass or stainless-steel tubes stuffed with glass fibre. Around the guard heater is the inner guard heater; on the outer sides of the specimens are the cold plates; and around the cold plates are the auxiliary cold plates. Around this stack are the outer guard heater and environmental chamber, which contains a cooling shroud. The cold plates and heaters were constructed out of anodised aluminium, which was done to promote conductive and radiative heat transfer. The group modified the cooling system to run an inter-connected cooling loop as opposed to the independent systems with which the system came packaged. Differential thermocouples are connected to each plate, and the guards measure each plate's temperature. The temperature data was used to calculate the thermal conductivity along with the control circuitry. Lastly, the auxiliary heaters, guards and environmental chamber were implemented strictly to prevent radial heat flow and external influences on the system (Smith, Hust & VanPoolen, 1982). It should be noted that this device pertains to insulation materials and not fluids.

**Figure 2.7: Cross section of the modified guarded hot plate (Smith, Hust & VanPoolen, 1982)**

In recent developments, Choi and Eastman used a GHP apparatus when they discovered nanofluids in 1990. The machine was based on Challoner and Powell's device (Choi & Eastman, 1995). In 2013 Raush *et al.* (2013) attempted to create a GHP capable of measuring the thermal conductivity of gases, liquids and solids. The device had a similar setup as that of Choi and Eastman in that the device consisted of a cold plate, hot plate and guard plate. The plate also

included a Peltier element for cooling and micrometre screws for adjustment. A cross-section of the device is presented in **Figure 2.8**. The cold plate is connected to the Peltier for cooling, and the hot face is connected to a set of fins for cooling. A two-part guard system ensures heat flow through the sample area. The top guard plate is heated to the same temperature as the hotplate to ensure no bi-directional heat flow through the sample and a guard ring around the entire setup. The guard ring comprises an inner guard ring and an outer guard ring, both in place to mitigate the effects of ambient conditions. Heating to the system is provided by a constant current source to the system via a resistive heating element embedded in the hot plate and cold plate. The authors noted that the hot plate was intentionally placed above the cold plate to mitigate the likelihood of convection in fluid samples.

The top assembly (hot plate, guard and micrometre screws) can be removed to clean the system between tests quite easily. The entire system is then placed within an environmental chamber for sub-ambient tests. A custom-made programme was generated to control the system through PID control schemes for cooling, heating and the guard heater to ensure steady-state conditions. The PID is fed information from the DC power supply, thermostats and a digital multimeter. With this setup, the authors could achieve a 5% deviation from reference data for water, Toluene, air and polytetrafluoroethylene (PTFE). The authors note that although the GHP could not achieve uncertainties similar to that of transient methods, its ease of use and accuracy make it a viable testing methodology for various materials (Rausch *et al.*, 2013).

**Figure 2.8: Cross section of GHP apparatus for fluids and solids (Rausch *et al.*, 2013)**

The guarded hot plate is one of the most commonly employed methods of testing in various fields due to its simplicity and the fact that it is considered an absolute method because the thermal conductivity is measured directly from the value obtained from the device (Yüksel, 2016). The uncertainty of the measurements of the GHP is approximately 2% at low temperatures; beyond this, the heat losses to the environment become greater when compared to other means of measurement, such as the thermal comparator (tec-science, 2020). A further advantage of the GHP is the standardisation in countries such as the US (ASTM C 177-63), Britain (B.S 874:1965) and Germany (DIN 52612) (Yüksel, 2016).

The primary disadvantage of the GHP is the long testing times, as it takes a relatively long time for the system to attain a steady state; however, this statement is true for all steady-state techniques. Another disadvantage is that the contact resistance between the thermocouples is a potential source of error in readings. The final disadvantage is that the recorded results of approximately 20 GHPs diverged significantly from reference values ranging from 13 to 16% (Yüksel, 2016).

In conclusion, the GHP is primarily used for the testing of the insulation; however, it is just as capable of measuring the thermal conductivity of other substances. Furthermore, due to the GHP being an absolute method that

significantly reduces computation, it is relatively simple to fabricate and operate. It is also evident that there are myriad contributing factors to the thermal conductivity enhancement of nanofluids. Some of these can be controlled, such as the manufacturing method and combination of surfactant, base fluid and nanoparticle employed. There are also inherent challenges in the means of testing that need to be overcome, such as gravitational effects, whether a testing method is considered obtrusive or not, and the onset of natural convection within the testing chamber. These challenges need to be accommodated in the design, and uncertainty in the results must be minimised.

### **3 CHAPTER THREE: Design and Fabrication**

The proceeding chapter will delve into further depth of the design and fabrication of the guarded hot plate apparatus. The design will be based upon that of Challoner and Powell, as described in the literature review, and will include modifications such as those made by Rausch to make additional observations.

#### **3.1 Design**

The present design is similar to that of Challoner and Powell; however, Stephen Choi provided brief dimensions for the apparatus used in the initial study of nanofluids. According to Wang, Xu and Choi (2008), the GHP setup consisted of copper plates with a surface area of 9.552 cm<sup>2</sup>, which equates to a diameter of 34.874 mm. Three glass spacer rings separate these with a thickness of 0.9652 mm. These spacer rings make  $\Delta x$  equate to 2.8956 mm. The guard is constructed of aluminium and heated electrically via a resistance heater. Both copper plates have holes of 0.89 mm in diameter drilled into them to accommodate E-type thermocouples; it is not stipulated how deep these holes are drilled. In total, 14 thermocouples were used to measure the temperature differences. The researchers noted that their primary goal was to minimise the temperature difference between thermocouples on each plate. The present, depicted in Figure 3.1, consists of the GHP apparatus, a GW Instek gps 3303 power supply and the Agilent 34970A data logger. The GHP apparatus consists of a frame, cold plate, hot plate, guard heater, water cooling loop and Arduino microcontroller-controlled PID circuit. Each will be discussed in greater detail in subsequent sections.

**Figure 3.1: 3D rendering of apparatus**

The apparatus overall consists of a frame, aluminium backplate, the core/stack assembly, rails, guard heater, fan cowling and water-cooling loop. The core assembly is mounted to the aluminium backplate via a stainless-steel retention plate, which also serves to align the thermocouples on the hot plate with their corresponding mate on the cold plate. The retention plates are bolted to nylon spacers. The bolts are long enough to hold the spacer plates but short enough that the bolts do not come into contact; this is done to prevent conductive heat transfer from the hot plate to the cold plate. On the face of the aluminium back plate, fibreglass insulation is placed to prevent heat from seeping through the sides of the cold plate. In the centre of the aluminium plate, a nylon spacer ring isolates the copper from the aluminium and creates a small air pocket to further insulate the cold plate. The aluminium back plate is bolted to the stainless-steel frame via a section of equal leg right angle ss304. On the frame are a series of slotted holes that allow for minor adjustments of the rails and aluminium back plate.

Additionally, a mounting plate is bolted to the frame's rear to accommodate the water-cooling loop's radiators. A vesconite ring separates the hot and cold plates. The vesconite ring has grooves machined into it to accommodate a nitrile cord; this acts as a means of sealing the testing cavity and preventing leakage of the fluid samples. The bulk of the apparatus was fabricated from SS304. This material was selected for its anti-corrosive properties.

For the current setup, the volume inside the vesconite ring amounts to 7.5 ml of fluid. This equates to an  $\Delta x$  of 5.68 mm. It was possible to create a simplified thermal circuit base formulated from the geometry of the stack assembly, which can be seen in Figure:

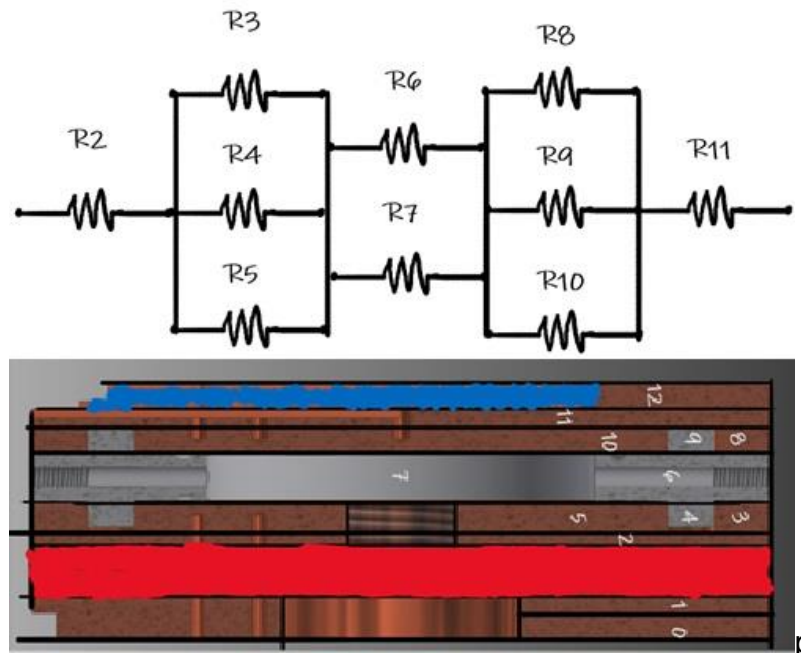

Figure 3.2: Thermal resistance circuit of stack assembly

The thermal resistance was calculated for each section using the following formula:

$$R = \frac{\Delta x}{kA} \tag{3.1}$$

Where:

R= Thermal resistance

$\Delta x =$  Thickness  
 $k =$  Thermal conductivity  
 $A =$  Area

Based on Equation (3.1), each value can be calculated individually. Due to the circuit having parallel and series resistive elements, the total resistance can be calculated using the following formula:

$$R_T = R_2 + \left(\frac{1}{R_3} + \frac{1}{R_4} + \frac{1}{R_5}\right)^{-1} + \left(\frac{1}{R_6} + \frac{1}{R_7}\right)^{-1} + \left(\frac{1}{R_8} + \frac{1}{R_9} + \frac{1}{R_{10}}\right)^{-1} + R_{11} \quad (3.2)$$

Next, the temperature differential can be calculated based on the power input into the system using the following formula:

$$\Delta T = R_T Q \quad (3.3)$$

Analysing the ideal system will make it possible to determine the losses from the system during testing and commissioning. For the analysis, it was assumed that the contact resistance would be negligible, that there was no heat loss radially and that there was no fluctuation in the supplied power to the hot plate. The thermal conductivity for each material can be found in **Table 3-1**:

**Table 3-1: Material properties**

Material	Thermal conductivity	Reference
Copper	385	(Thermtest Inc., 2022)
Water	0.65	(Thermtest Inc., 2021)
Vesconite	0.25	(Vesconite, 2019)

**Table 3-2** includes all details of the system. The dimensions and areas were extracted from the 3D model generated within the Solidworks draughting package.

**Table 3-2: Stack assembly dimensions**

Part	Section	Area (mm <sup>2</sup> )	Thickness (mm)
Hot plate	2	4656	2
Hot plate	3	1297	3
Vesconite ring	4	967	3
Hot plate	5	2391	3
Vesconite ring	6	3458	5.68
Water sample	7	1320	5.68
Cold plate	8	1297	3
Vesconite ring	9	967	3
Cold plate	10	2513	3
Cold plate	11	4599	2

From these dimensions, it was calculated that the system has a total thermal resistance of 3.4 K/W, which means a temperature differential of 3.3 K between the resistive heater and the cold plate. The numerical calculations were compared to an FEA analysis of the core assembly.

The model was exported from Solidworks to Abaqus. The properties in Table 3-1 were assigned to the relevant parts. Next, the assembly was constrained so that the contact solver could be used to determine the relevant interactions. A mean contact resistance of 1 was used throughout all interactions. In the initial step, a temperature of 20 °C was applied. Two boundary conditions were inserted, one on the interface of the cold plate to the Peltier element of 20 °C and one on the interface of 23.5 °C on the interface of the hot plate and the cartridge heaters. The temperature of 23.5 °C was selected based on the calculations in the previous section. A load of 1 W was applied to the interface of the heat cartridges and the hot plate. The simulation was then run.

**Figure 3.3: Nodal temperatures of stack assembly**

Figure 3.3 shows the nodal temperatures through the core assembly. It should be noted that this analysis included the pressure transducer to prove that there would be little parasitic drain through the pressure transducer to the surrounding. It is observed that the hot plate achieves a uniform temperature, along with the cold plate achieving a uniform temperature. To verify the uniformity of the temperature distribution, nodal temperatures were observed via the query tool in Abaqus at the point at which the thermocouple interfaces with the hotplate and cold plate and the surface temperature of the hot plate and cold plate. These results are presented in **Table 3-3**.

**Table 3-3: FEA query results**

Part Instance	Node ID	Orig. Coordinates			Nodal temp
		x	y	z	
Hot plate	21	23.3	50.5	73.9	23.5
Water sample	64287	23.3	49.5	73.7	23.2
Cold plate	289117	23.1	43.8	73.8	20
Cold plate	3	23.3	42.8	73.9	20
Cold plate	99102	23.3	39.8	70.9	20

The heat flux can be observed in **Figure 3.4**: the bulk of the heat flux flows through the sample; however, it should be noted that this may vary according to the medium placed within the sample area. The difference in the temperature that

the thermocouples and the actual temperature will record will be 0.3035 °C which, given the accuracy of the K-type thermocouples, is virtually negligible. The same can be said for the cold plate.

**Figure 3.4: Heat flux analysis of stack assembly**

It is clear that there is an agreement between the FEA analysis and the thermal circuit generated by a numerical method.

### **3.1.1 Hot plate**

The hot plate consists of a copper block with seats drilled for the thermocouples, a tapped hole for the pressure transducer, holes drilled at 60-degree angles to accommodate three heating cartridges, a groove for the O-ring and a groove for the separation ring. Copper was selected as the material of choice due to its relatively high thermal conductivity. Due to the complexity of the shape, there is no shape factor for the hot plate; as such, the approach taken was that of an FEA analysis, which was validated via a simplified heat resistance circuit. The thermal resistance circuit is a truncated version of the circuit created in section

3.1. A graphical representation of what has been described is presented in **Figure 3.5**, and a 3D rendering in Figure 3.6.

**Figure 3.5: Orthographic projections of the hot plate**

A preliminary analysis of the hot plate alone, of mass 0.566 kg, shows that raising the temperature of the hot plate (by a single degree kelvin) would require 214 W; however, given the fact that each heating cartridge can produce 40 W and a total of 120 W altogether, the total time to achieve this temperature change would be 1.78 seconds. Because of the limitations of the GW instek power supply, a constant 1 W will be supplied, which means heating the hot

plate from an ambient temperature of 20 °C to 23.5 °C would take 12 minutes and 29 seconds.

**Figure 3.6: 3D rendering of the hot plate**

The material selected for the hot plate was copper due to the high thermal conductivity of copper. The hot plate allows for the heat supplied to be evenly distributed throughout the hot plate; this was confirmed in the FEA analysis and through testing. The FEA analysis was conducted using Abaqus. The initial boundary conditions were set as follows: the surface of the interface between the heating cartridges and hot plate temperature was set at 20 °C; and the heat flux was set at 1 W at the surface of the holes drilled for the heating cartridges. The initial temperature was set at 20 °C, considered ambient temperature, and 120 W was the sum of the heat applied via the three 40-watt heating cartridges. Note should be taken that the FEA analysis neglects the PID control implemented to maintain the temperatures of the plates. As seen from the snapshot in **Figure 3.7**, temperatures rise substantially above the heating cartridges, and the heat is then dissipated radially throughout the hot plate. These localised hot spots dissipate, and the whole plate reaches a normalised temperature. Further assumptions made during the FEA analysis were that

there was no heat loss to ambient; this assumption was made due to the guard heater being set at the same temperature as the hot plate, which would eliminate radiative heat transfer between the two. The thermal conductivity was maintained constant as the hot plate's temperature would be close to ambient due to limitations imposed by the power supply.

**Figure 3.7: FEA analysis of hot plate**

The device was then tested with similar conditions. These results were compared to a thermal circuit constructed per **Figure 3.2**.

Using the thermal resistance formula, which is just the reciprocal of the thermal conductivity formula, it was possible to ascertain the temperature drop across the copper hot plate to the surface, which was determined at 0.003 K.

### **3.1.2 Cold plate**

The cold plate was similar in design to that of the hot plate, the only significant differences were that there was no pressure measurement from the plate, and the heating cartridges were substituted for that of a Peltier module which acts as the heat pump. Furthermore, the copper plate was made smaller to reduce the effects of the heat capacity of the cold plate. Otherwise, the cold plate maintains a groove for the separation ring, a groove for the O-ring and a network of holes drilled for the thermocouples.

**Figure 3.8: Orthographic projections of the cold plate**

The cold plate has a mass of 0.226 kg; performing the same preliminary analysis as the hot plate, to drop the temperature of the cold plate by 1 degree requires the removal of 92.8 W from the cold plate, as per the calculations in Appendix A, given that the system would be in a temperature-controlled environment that would be maintained at approximately 20 °C. The FEA analysis of the cold plate was forgone as the analysis conducted on the core assembly was deemed sufficient. A closed-loop all-in-one (AIO) cooler was selected to remove the heat from the hot side of the Peltier element. This was done for two reasons, the first being that the water-cooling loop would facilitate more stable temperatures and the low maintenance requirement of the device. The liquid cooling loop inherently contains a radiator, pump and reservoir. The water-cooling loop would run continuously; however, the cold plate would be controlled via a PI control scheme integrated into the Arduino code. The temperature would be taken from the cold plate via a Max 6675 break-outboard and used as input for the PI controller. The PI controller would then generate a value that controlled the IRL520n MOSFET. The result of this loop would be an appropriate response to fluctuations in the temperature of the cold plate. The primary objective of the cold plate was to maintain a set temperature. A schematic of the cooling circuit is presented Figure 3.9.

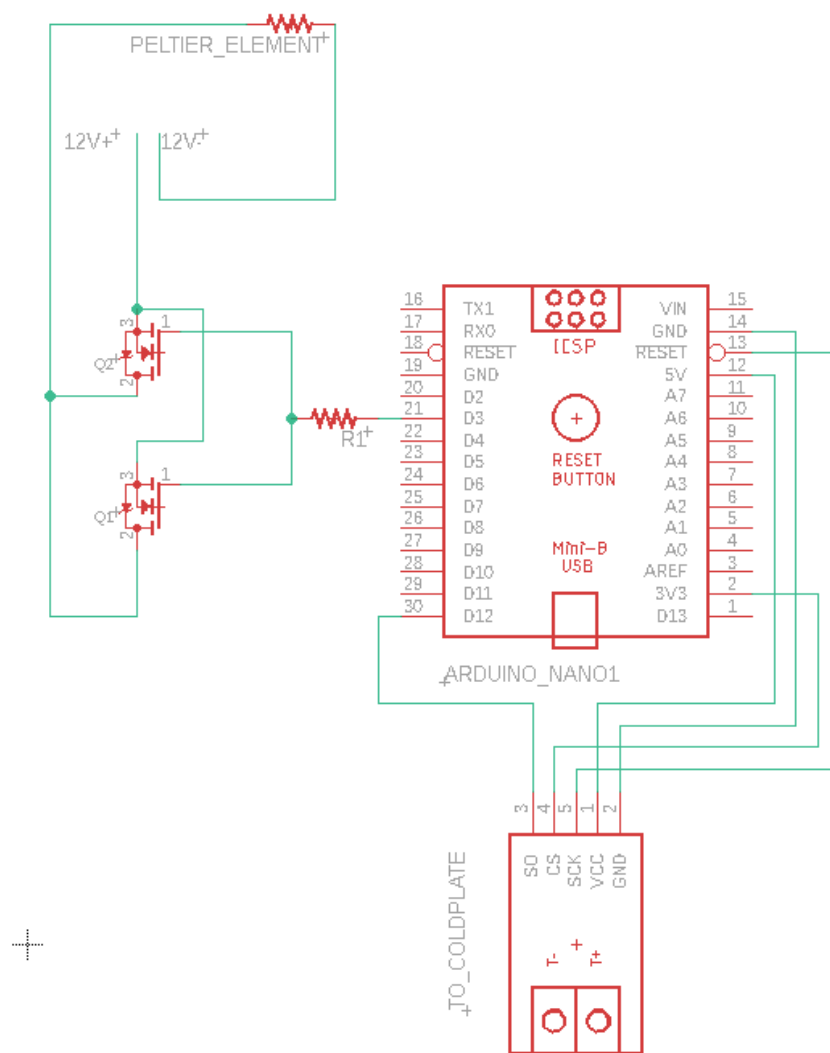

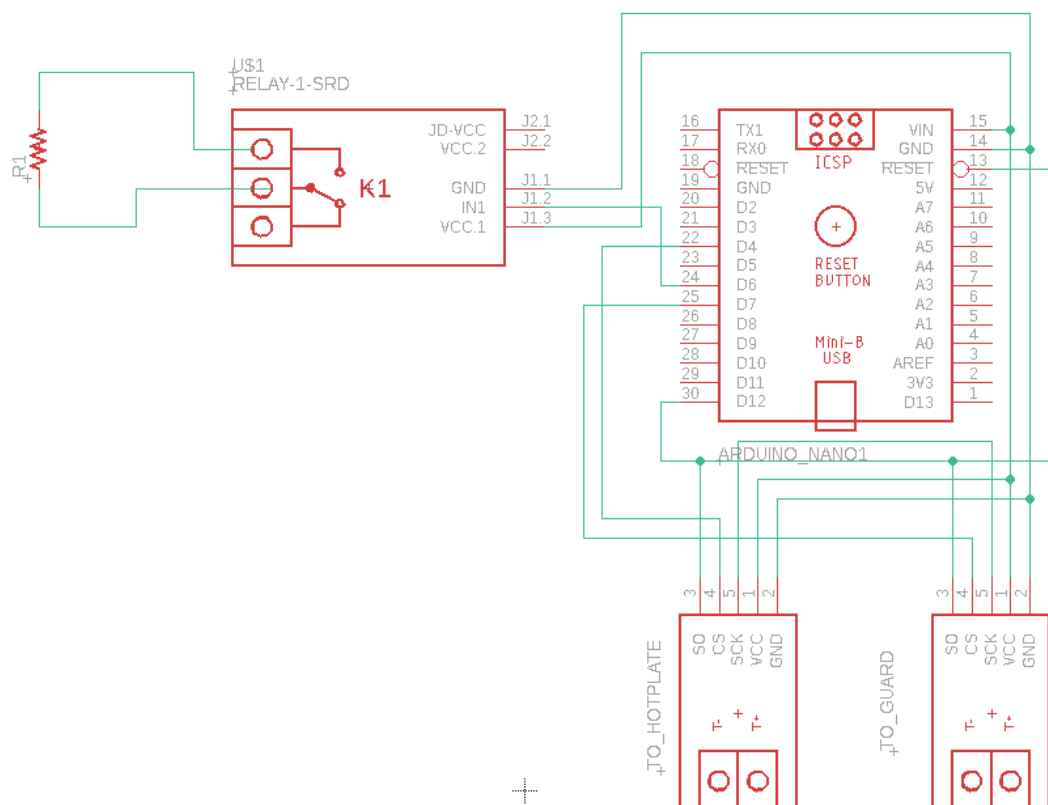

Figure 3.9: Schematic of the cold plate control scheme

### 3.1.3 Guard heater

The guard heater is particularly important as it fundamentally differentiates the guarded hot plate from the Lee disk method. Where the Lee disk method leaves the sample open to the atmosphere, the guard prevents heat loss from the hot plate to the surrounding. The guard is set to match the temperature of the hot plate to prevent radiative heat loss and heat loss through conduction or convection. The design was similar to that of the parallel plates; consequently, the total heat capacity was considered. For the guard, it was decided to use steel instead of aluminium because a larger mass would be required. The larger mass made the guard less prone to minor fluctuations allowing for a more consistent temperature. Helical grooves were machined into the guard heater to facilitate a nichrome wire that would be wound around it. On the base of the

guard heater, a mounting bracket was mounted to allow the attachment of two linear bearings. The linear bearings would then glide along two adjustable rails attached to the frame. The linear bearings would ensure the alignment of the guard heater around the stack assembly.

The nichrome wire would act as a resistive heater. The guard heater was controlled by a bang-bang controller, which was integrated into the Arduino microcontroller's code. The Arduino would take temperature measurements via two max 6675s. The temperature would then be used in a conditional 'if statement' within the Arduino code, which would control a relay that would allow the current to flow through the resistive element. A schematic diagram can be seen in **Figure 3.10** of the guard heater circuit.

**Figure 3.10: Schematic of guard heater**

### 3.1.4 Electronics

Aside from the laboratory power supply and data logger, ancillary electronics are embedded in the system to replicate steady-state conditions. Most of these

electronics have been briefly discussed in previous sections. Here further details will be provided. The complete schematic can be found In Appendix B, and the code can be found in Appendix E. The board design was based upon a design found on [electronoobs.com](http://electronoobs.com); however, the PID controller was deemed insufficient. Instead, a custom auto-tuning PI controller was implemented as the derivative function was subtractive and would result in a less responsive controller. The max 6675 temperature sensor was selected as the input for the PI controller and had a resolution of 0.25 °C. The Arduino nano was selected as the microcontroller due to its relative simplicity and small form factor. The IRL520n was selected due to its current limit and the fact that it is a logic-level transistor, which allowed the Arduino nano to control it via a PWM signal. As mentioned previously, a pair of MOSFETs and a relay controlled the cold plate and guard heater, respectively. The spec sheets for all components mentioned here are found in Appendix C. A circuit board was designed in KiCAD. Additionally, screw terminals were placed on the board to interface the circuit board and the external electronics to maintain the modular design.

### **3.1.5 Breakout boards connected to controller board**

The following section will discuss the breakout boards connected to the controller board. Breakout boards were selected as they would reduce the complexity of the PCB design and directly interface with the Arduino microcontroller with no further modifications required.

- *Max 6675 K-type thermocouple sensor*

Three Max 6675 were used on the main controller board, one for each of the temperatures found throughout the GHP. The Max 6675 has an on-board cold junction compensation and a resolution of 0.25 °C. The unit has a temperature range from 0 °C to 1024 °C (Maxim, 2002). The Max 6675 connected to the cold plate is the input to the PI controller that governs the cold plate temperatures. The Max 6675 connected to the hot plate and guard controls the on-off controller of the guard heater. The hot plate temperature is used as a set point and the guard heater temperature is established for comparison.

Figure 3.11: K-type thermocouple sensor (botshop.co.za, 2020)

- *Relay board*

The relay board was a 5-V breakout board used to implement the on-off controller. The board was selected to isolate the 5-V circuit from the high current 12-V circuit and prevent damage to the Arduino nano board.

Figure 3.12: 5-Volt relay board

- *Peltier element*

The Peltier element selected was a TEC12715. This element was selected due to its 154 W cooling capabilities.

- *AIO liquid cooling loop*

The liquid cooling loop is a generic all-in-one package with a dual-fan radiator.

- *Current shunt*

The current shunt was constructed of three 1  $\Omega$  resistors.

- *K-type thermocouples*

The thermocouples used to measure the temperatures were K-type thermocouples. The K-type thermocouple is constructed from nickel-chromium and nickel-alumel. They have a temperature range of -270 °C to 1260 °C. While the standard error for these thermocouples are +/- 1.1 °C, this can be reduced through calibration (REOTEMP Instrument Corporation, 2011).

### **3.1.6 External instrumentation for experimentation**

The GHP was used in conjunction with two external systems: the Agilent 34970A and the GW instek gps3303.

- *Agilent 34970A*

The Agilent 34970A is a data logger with a 6.5-digit display (22-bit resolution). The unit is coupled with a 20-channel multiplexer that uses reed switches. The multiplexer is capable of measuring 60 channels per second. The unit has a built-in cold junction compensation and an accuracy of 1.5 °C for K-type thermocouples. The accuracy at 1 V is 0.004 V. It should be noted that the thermocouple accuracy is in line with the standard measurement error of K-type thermocouples (Agilent, 2012). The data logger was used for all measurements from the GHP. All thermocouples were connected to channels 1 through 11 of the data logger. Channels 12 and 16 were used for voltage measurements across the current shunt and heating cartridges.

Figure 3.13: Agilent 34970A (Technologies, n.d.)

- *GW instek gps3303*

The GW instek gps3303 is a laboratory power supply. The power supply, with two channels, is capable of 0 to 30 V and 0-3 A. The unit has a ripple of 1 mVrms and a 3 mArms in a constant current configuration (GW instek, 2018). The power supply was selected due to the low noise on its output. Due to the device's limitations, it applied a limit on the power that could be applied to the heating cartridges.

Figure 3.14: GW instek gps3033 (Good Will Instrument Co., n.d.)

## 3.2 Fabrication

For fabrication, the cold and hot plates were sent for CNC machining through Gullwing engineering and all sheet metal parts were sent to SPP laser for CNC laser cutting and bending. The sheet metal parts include the frame, aluminium

back plate, radiator mount and mounting plates. The separation ring was machined from vesconite, and the guard heater was sent for turning once the parts were laser-cut and welded together. The parts sent for machining and laser cutting was manufactured as per the drawings in Appendix B. The apparatus was designed so that the entire assembly could be bolted together. This was done for modularity so that parts could be removed or adjusted during the prototyping phase. The electronics were all consolidated onto a single board and machined via a CNC router. The schematic generated in KiCad was used to create a DXF file that could be imported into a post-processing software. The post-processing software generated a g-code to plot the tool path of the CNC router. The holes were first peck drilled with a 0.8 mm bit, and then the traces were routed with a 1 mm milling bit.

**Figure 3.15: Milling of the controller board PCB**

### **3.3 Challenges**

Throughout the project, various technical challenges were faced. The first challenge encountered was that of galvanic corrosion. The corrosion occurred at the interface between the cold plate and the copper cold plate. To circumvent the corrosive effects, a nylon ring was placed between the interface of the two materials to mitigate direct contact between the two. Initially, the hot plate's current was similarly controlled via the Arduino microcontroller to that of the cold plate; however, this was later substituted for GW instek gps3033 due to the fluctuation in output from the IRL520n MOSFET. This resulted in a constant misreading of the current, which is vital for calculating the power input into the heaters.

The 1 mm milling bit used to machine the PCB could not route the pins for the Arduino nano. Thus all the traces to the pins of the Arduino were connected. An engraving bit was used to separate the pins to remedy this fault. The vias for the board were soldered into place to ensure the connection between the top and bottom traces.

Natural convection is where the denser parts of the fluid are overcome by gravity, and a convective flow develops within the fluid, and natural circulation takes place, affecting the fluid's thermal conductivity readings. Natural convection became apparent only through testing, whereby the thermal limits of the cold plate were reached much faster than anticipated. To circumvent the formation of natural convection, the entire test apparatus was positioned so that the cold plate was at the bottom and the hot plate was at the top.

**Figure 3.16: Orientation of final GHP setup**

The guard heater acted as an inductor due to the nichrome wire used as a heat source coiled around the guard. This, in turn, acted as an inductor. The ground wire was coiled reverse to the initial coil to circumvent this inductance.

## 4 CHAPTER FOUR: Testing and commissioning

For the commissioning and testing of the experimental setup, each component was tested individually and then assembled. There are two methods for the calibration of thermometers: fixed point and comparison calibration. Fixed point calibration entails a point bath or furnace. Fixed point calibration is primarily used for temperature measurements through secondary measurement devices such as thermometers. The advantage of fixed-point calibration is that it produces low uncertainties but is not sufficient for an ISO9000 certification. Comparison calibration entails the comparison of one measurement method to a second means of measurement. Comparison calibration is the most frequently employed method for ISO9000 certification (de Silva, 2002).

Before testing could be conducted, it was necessary to calibrate the thermocouples. To do this, crushed ice was placed in a container and filled with water; the container was left to stand in ambient conditions for 10 minutes to allow this ice to melt, which is precisely 0 °C. The water was then drained, leaving the ice wet. The thermocouples were then placed into the container, and readings were taken every 10 seconds for five minutes (see **Figure 4.1**). Next, the thermocouples were placed into a boiling kettle to verify the accuracy of the thermocouples. It was determined that the error recorded per thermocouple was within the specified tolerance. The calculated error was within 1.5%. The aforementioned methodology is in line with those outlined for ISO9000 certification. All results were compared to those of an RTD and mercury thermometer.

**Figure 4.1: Left: cold temperature calibration; Right: hot temperature calibration**

The results of the cold bath test can be seen in Table C-7. It was found that there was an average standard deviation of  $0.022126\text{ }^{\circ}\text{C}$  and an average temperature reading of  $-0.10313\text{ }^{\circ}\text{C}$ . The median was  $-0.10557\text{ }^{\circ}\text{C}$ . The mercury thermometer had a reading of  $0\text{ }^{\circ}\text{C}$  and the RTD registered a value of  $-0.1\text{ }^{\circ}\text{C}$ . The results of the hot bath test are presented in Table C-8 in the appendix. A standard deviation of  $0.039719\text{ }^{\circ}\text{C}$  and a median of  $98.91497\text{ }^{\circ}\text{C}$  were observed. The average boiling water temperature was found to be  $97.91771\text{ }^{\circ}\text{C}$ . The mercury thermometer had a reading of approximately  $99\text{ }^{\circ}\text{C}$  and the RTD registered a value of  $98.9$ . Based on this, the calibration of the thermocouples were deemed acceptable. It was noted that the Max 6675 had an error in measurement of approximately  $1\text{ }^{\circ}\text{C}$  and as such, the code was compensated to account for this error.

The current shunt was configured into a 4-wire output mode. The wires of the current shunt were connected to the data logger and the resistance was measured. The resistance value was found to be  $0.00758\ \Omega$ . This value remained constant for the duration of the test. The resistance of the current shunt will be used to calculate the power input on using Equation (4.1) where the current is equal to the voltage difference across the current shunt

divided by the resistance value. The current is then multiplied by the voltage drop across the heating cartridges.

$$P = I.V$$

**(4.1)**

The first component tested was that of the hot plate. The hot plate was encased in Styrofoam, and controlled power was supplied. The hot plate was left for one hour under these conditions before temperature readings were taken via the Agilent data logger. These results were compared to the results from the FEA analysis, as discussed in the preceding section 3.1.1. The cold plate was placed into similar conditions; however, this test was conducted to begin tuning the PI controller. Once an appropriate proportional response was tuned, the hot plate was then placed in direct contact with the cold plate to begin further tuning. The PI controller was tuned by applying sufficient power to generate a hot plate temperature of at least 10 degrees higher than that of the cold plate. The cold plate was given a set point of 20 °C. The relevant proportional and integral values were adjusted incrementally; between adjustments, the system would be given 40 minutes to equalise before values were adjusted until a desirable control was found. The next component tested was the guard heater. The guard heater was left open to ambient conditions; the set point was then set and allowed to heat up until the desired temperature. The test found that the set point of the guard plate needed to be offset to compensate for the thermal lag that would cause the guard heater to overheat.

Once each component had been tested in isolation, the system was brought together. The PI controller was fine-tuned with a water sample in the test cavity. This was done to smooth out temperature fluctuations that would throw the system out of a steady state. With the water sample in the system, a continuous 1 watt of power was provided to the heater. The system was left to run for one hour to ensure a steady state condition. The temperatures were then taken via the data logger every minute for 15 minutes. Once the test was complete, the system was turned off and allowed to return to ambient conditions. The water was then replaced with a fresh sample, and the test was then run again with this procedure a total of five times. These results were then analysed and compared to the ideal model used in Chapter 3.1. To calculate the losses, the power

supplied to the heating cartridges was recorded and the temperatures were recorded. The temperature differential was used to calculate the actual heat flux through the sample based on Equation (3.3). The measured power could then be calculated based on Equation (4.1). The actual was subtracted from the measured to obtain a correction factor. A 17.5% loss in the system was determined and a correction factor would need to be applied to compensate for these losses. The calculations can be found in Appendix A: Calibration Calculations.

Figure 4.2 presents a graph depicting the hot temperatures recorded for each test run. From this, it was determined that temperatures tended to fluctuate within an allowable limit of  $\sim 0.25\text{ }^{\circ}\text{C}$  for the system. The rest of the fluctuations could be due to noise, and a similar noise was present when doing the calibration tests for each thermocouple.

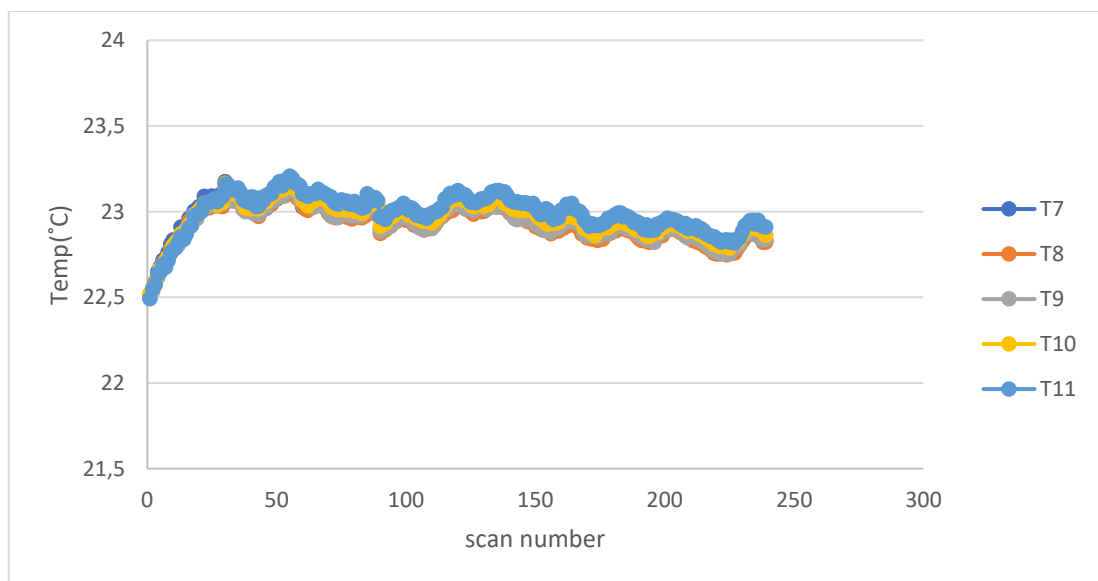

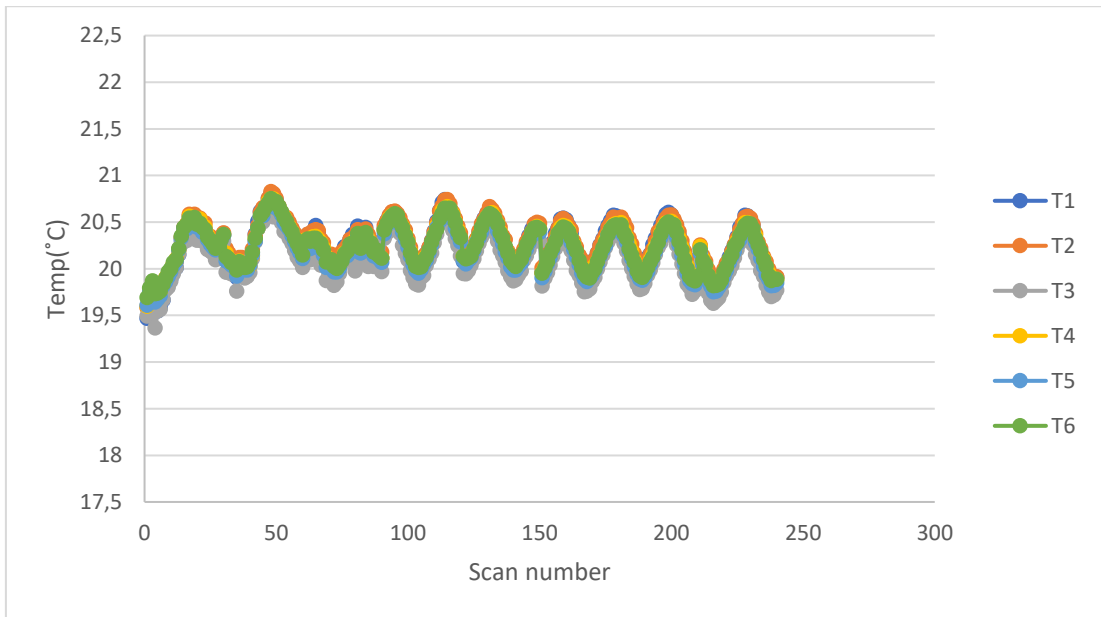

Figure 4.2: A graph of the hot plate temperatures recorded

From the cold temperatures, we can see far more significant fluctuations; this is due to the resolution of the Max 6675 that provides the temperature data to the PI controller. It should be noted that this does indeed influence the calculated thermal conductivity.

**Figure 4.3: A graph of cold plate temperatures**

An additional test was conducted on a water sample. The test yielded a mean thermal conductivity of 0.612 W/mK at a mean temperature differential of 2.722 °C. The test was based upon the averages of the power and temperature differentials to eliminate the variance between the samples of results. The averages can be seen in **Table 4-1**. The test was started prematurely to identify if there were any external influences on the system; it was found that there is a spike in the calculated thermal conductivity, which appears to correlate with a spike in the ambient air temperatures. This could result from the back plate being open to the environment, thus making the system susceptible to external influence. In addition, there is a rise in the calculated thermal conductivity when the cold plate heats up prior to the PI controller compensating for the temperature rise. Despite this, the mean thermal conductivity is within range of the reported results. There was a 2.3% difference between the reported thermal conductivity and the measured thermal conductivity. Thus the accuracy of the GHP is far greater than that reported by Yüksel.

**Table 4-1: Parameters used for water thermal conductivity**

Parameter	Value
$\Delta T_{=}$	2.722 °C
$P_{=}$	0.881 W
$R_{\text{water}={}$	7.19 W/mK
$\Delta L_{=}$	5.68 mm
$A_{f=}$	0.001 m <sup>2</sup>

Furthermore, the results from the water calibration test were compared to the results of the FEA analysis. There was a difference of 0.372 °C between the calculated temperature difference. This was a variance 11.9% and can be compensated for by the power loss to the GHP's surroundings.

## **5 CHAPTER FIVE: Discussion of results**

For testing, the GHP was compared to the reported results of ethylene glycol and then a nanofluid, i.e., cobalt oxide ( $\text{Co}_3\text{O}_4$ ) nanoparticle suspended in ethylene glycol. The experimental procedure employed for each experiment will be outlined and discussed.

### **5.1 Experimental procedure**

Prior to testing and filling the fluid cavity, the guard heater was rolled back, which was then removed via the four bolts compressing the stack/core assembly. The vesconite ring could then be removed and thoroughly cleaned in deionised water, and the same would be done for the hot and cold plates. The part would then be allowed to dry before reassembly of the stack assembly by reversing the previous steps. Once assembled, the M3 bolt at the top would be removed, and the sample material would be injected into the testing chamber. The thread tape on the M3 bolt would be replaced; this occurs between each test to prevent cross contamination of samples. The system is left to attain thermal equilibrium before the power supply is turned on, along with the Meanwell 12 V power supply. The system was left for approximately one hour to attain steady state conditions before the Agilent 34970A is manually turned on, and readings would be taken every 30 seconds for 15 minutes. When testing was completed, all power supplies would be turned off, and the system would be allowed to cool. At this point, the sample could be removed, or subsequent tests could be conducted following the previous steps. To remove the sample from the testing area, the top M3 bolt would be left in whilst the bottom M3 screw would be removed; the vacuum within the testing area would hold the fluid in place whilst a container is placed underneath the opening in the vesconite ring. The top bolt was then removed, and the fluid flows, as there would no longer be a vacuum. For all tests, constant power of 1 watt was applied due to the limitations of the equipment.

## 5.2 Results

The procedure above was followed for the ethylene glycol samples; however, additional steps were taken for the nanofluids to stabilise the suspended nanoparticles. For testing purposes, two samples of cobalt oxide nanofluids were procured from the chemical department of CPUT. The nanoparticles were manufactured through a CRM method to produce a nanopowder. The nanopowder was then placed into the ethylene glycol and sonicated for approximately one hour. Two samples were produced. The first marked A3 contained nanoparticles with a volume fraction of 0.5%. The second marked B3 contained nanoparticles with a volume fraction of 1%. It should be noted that these are comparatively high-volume fractions.

### 5.2.1 Glycol

The glycol sample was taken from the same batch as the one used to produce the nanofluid. **Figure 5.1** shows the temperature differentials and power plotted. It can be seen that the system has attained steady state conditions as of scan 10. Thus the averages of the recorded results will be calculated from that point forward. The averages can be seen in Table 5-1. Two separate tests, conducted with different samples, established a baseline with which the nanofluid could be compared to see if there would be an increase in thermal conductivity. In the first test, presented in Figure 5.1, it can be observed that the mean temperature differential between the two plates is 4.46 °C. This equates to a mean thermal conductivity of 0.247 W/mK.

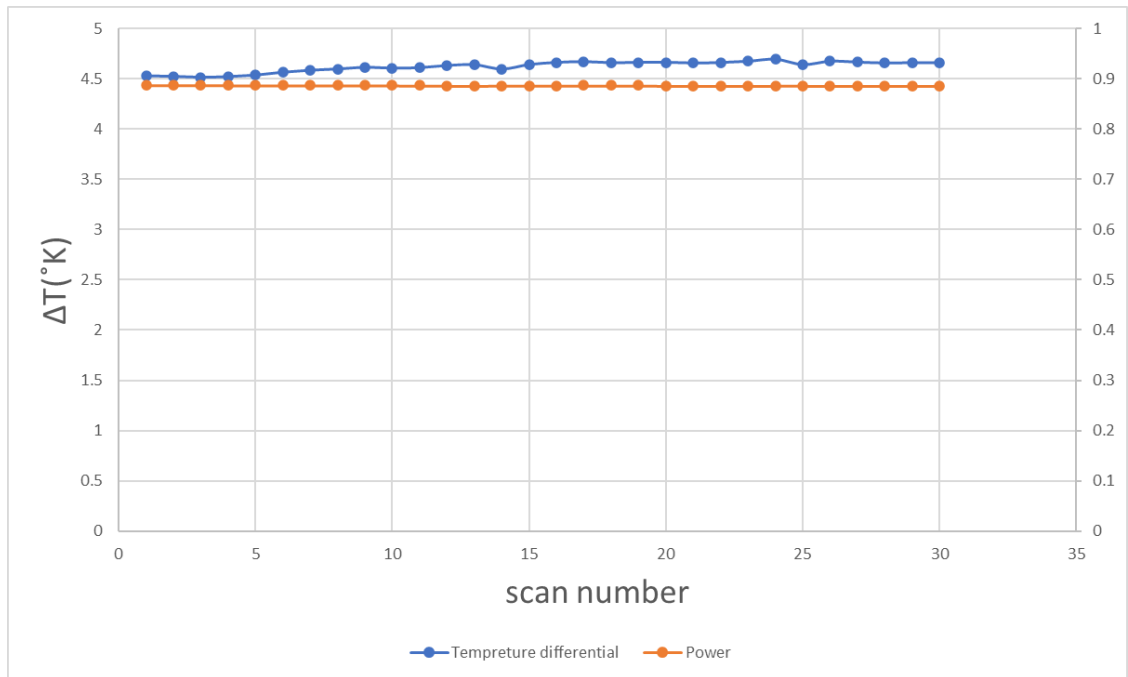

**Figure 5.1: Power and temperature differential of glycol test 1**

**Table 5-1: Average values used glycol test 1**

Parameter	Value
$\Delta T =$	4.468 °C
$V =$	1.077 V
$I =$	0.997 A

In the second graph, similar results to that of the first are evident; however, two minor disturbances can be seen in the graph due to the response of the PI controller. This sample reached a mean temperature differential of 4.65 °C, and a mean thermal conductivity of 0.208 W/mK was calculated as per the values of Table 5-2.

**Figure 5.2: Recorded results of glycol test 2**

**Table 5-2: Average values used glycol test 2**

Parameter	Value
$\Delta T =$	4.650 °C
$V =$	1.077 V
$I =$	0.997 A

Compared to the reported results of 0.254 W/mK, there is a 10.5% deviation from the results recorded during testing. These results will be used as a baseline moving forward for the comparison of the cobalt oxide nanoparticles.

### 5.2.2 Cobalt oxide nanofluid

The first sample tested was the sample with the lower volume concentration. It should be noted that only a single test was run as subsequent tests yielded near identical results to that of ethylene glycol. This is most likely due to the lack of surfactants present in the nanofluid to act as a suspending agent. Furthermore, there appears to be very little particle size control in the sample, and gravitational effects overcame the particles. The gravitational effects caused agglomeration and forced the particles to settle on the surface of the cold plate, leaving nothing but ethylene glycol as the heat transfer medium. Figure 5.3 data

show that the temperature differential begins to rise towards the end of the test, and the thermal conductivity drops. As previously stated, this is most likely due to the gravitational effects. For this test, there was a mean temperature differential of 4.45 °C, and the mean thermal conductivity was calculated at 0.255 W/mK.

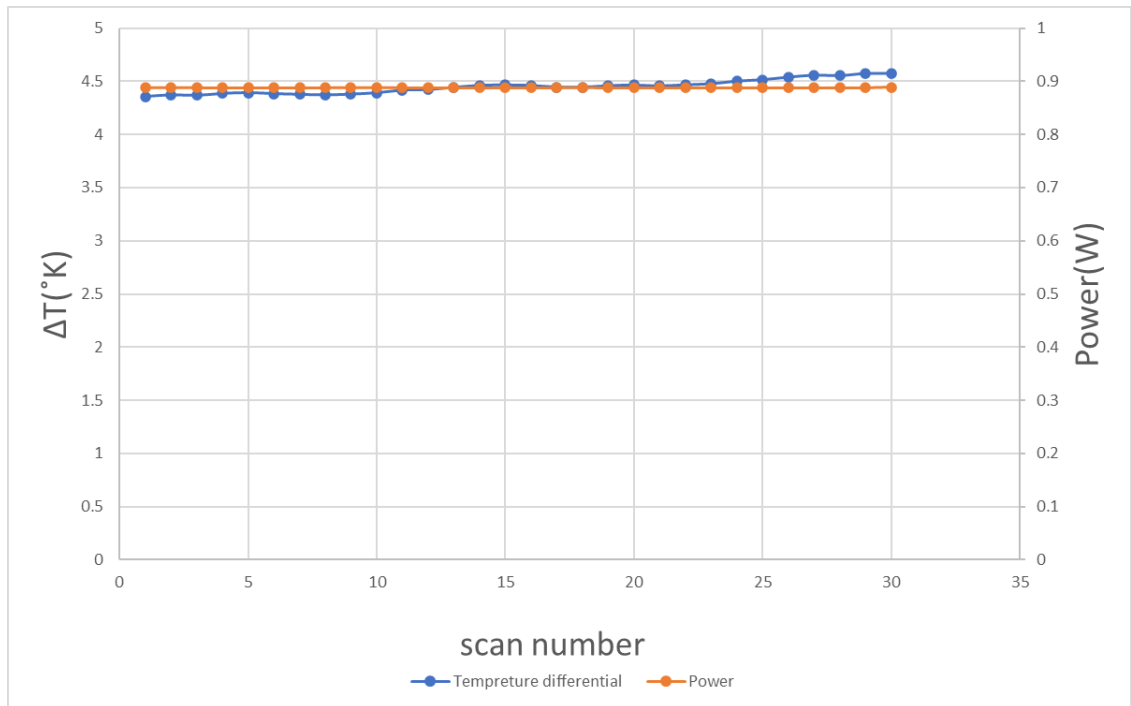

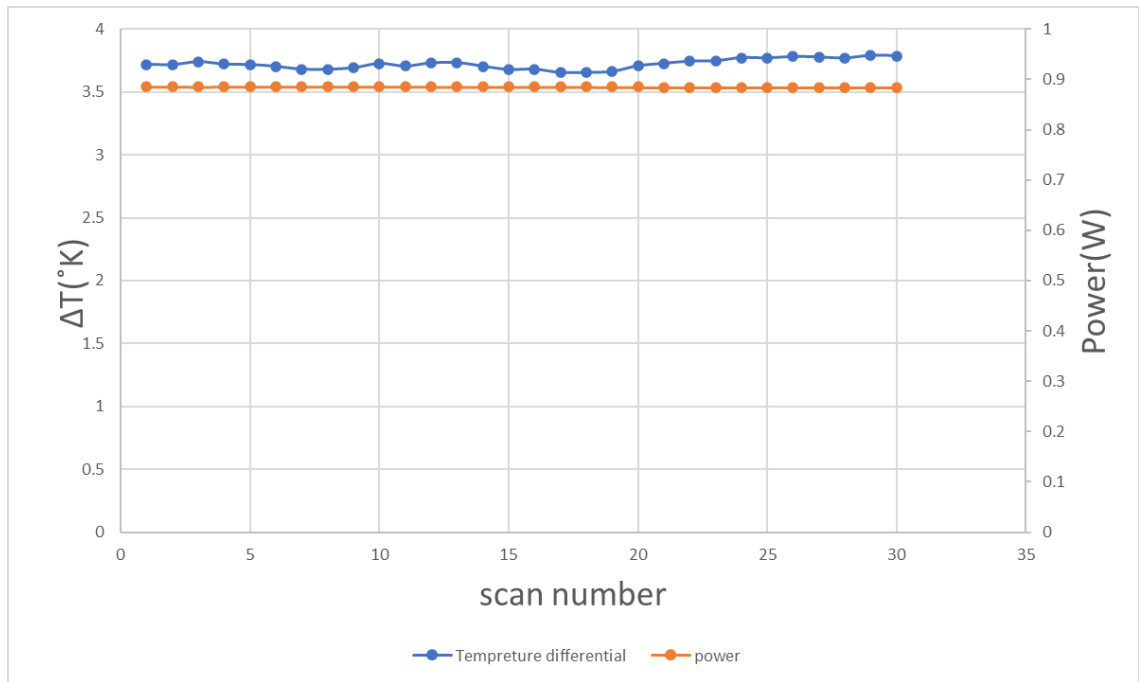

Figure 5.3: Recorded results of sample A3

Table 5-3: Average values used for sample A3

Parameter	Value
$\Delta T =$	4.44 °C
$V =$	1.08 V
$I =$	0.996 A

The following sample tested was the sample with a higher volume concentration factor. The sample appeared more stable than its predecessor, and the mean temperature differential was calculated at 3.72 K while the mean thermal conductivity was calculated at 0.454 W/mK. Toward the end of the test, the thermal conductivity began to drop due to agglomeration.

**Figure 5.4: Recorded results of sample B3 test 1**

**Table 5-4: Average values used sample B3 test 1**

Parameter	Value
$\Delta T =$	3.722 °C
$V =$	1.077 V
$I =$	0.996 A

The second test of the same sample yielded similar results, albeit marginally higher. The mean temperature differential was found to be 3.68 °C, and the mean thermal conductivity was calculated as 0.467 W/mK. It should be noted that a slight fluctuation in temperature is noticed after 15 minutes. The calculated thermal conductivity began to drop again due to the settling of the nanoparticles.

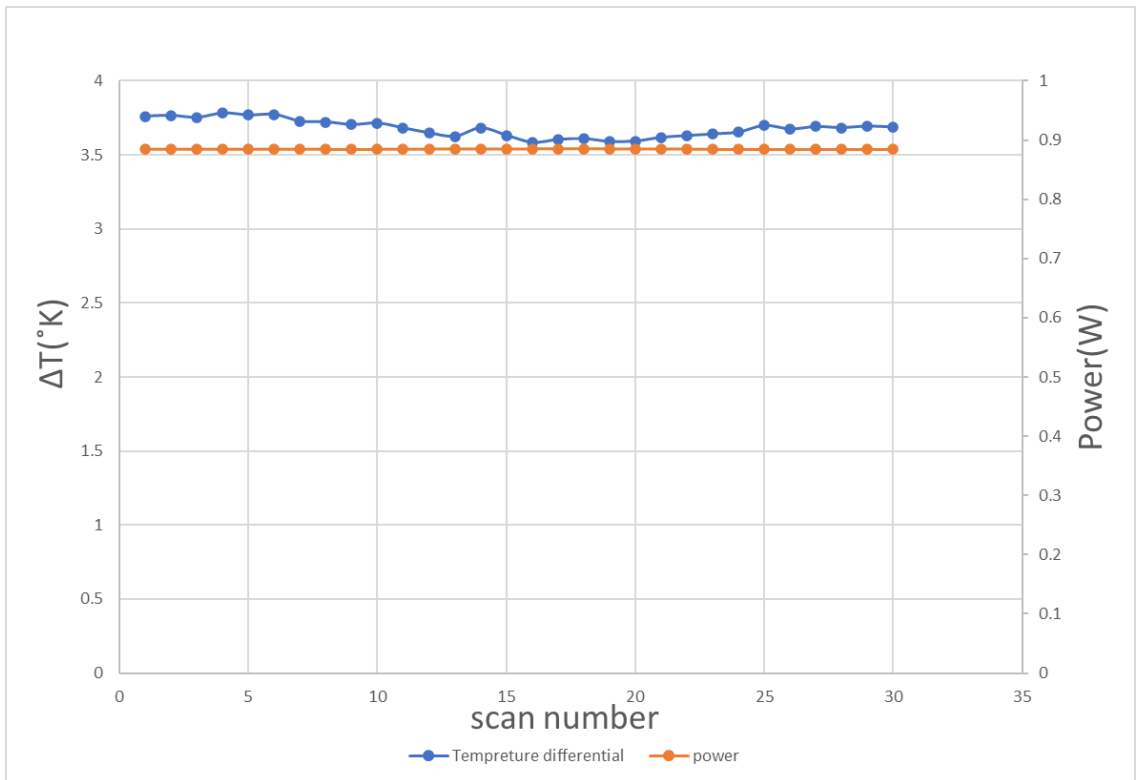

Figure 5.5: Recorded results of sample B3 test 2

Table 5-5: Average values used sample B3 test 2

Parameter	Value
$\Delta T =$	3.679 °C
$V =$	1.076 V
$I =$	0.995 A

### 5.3 Discussion

As seen in the results, the addition of nanoparticles yields a higher thermal conductivity. However, it should be noted that nanoparticles produced through CRMs typically tend to be less stable than those produced from optical methods such as laser ablation. The particles may tend to agglomerate, and the smaller particles remain suspended. This may have been the case for sample B3. The settling of the nanoparticles could be further agitated by the long testing times and the time taken for the system to obtain steady-state conditions.

Another observation made during testing was the rapid decay of the samples provided. Figure 5.6 shows a comparison of the sample directly after sonication (on the right) and after approximately four hours (on the left). Sample B3 remains slightly opaque; it is evident that gravitational effects have taken effect.

As for sample A3, the nanofluid has become very clear. This settling could explain why sample A3 degraded in the test cavity. It should also be noted that during cleaning, a layer of cobalt oxide was present on the cold plate as well, as such precautions were taken to prevent skin contact. As stated in the literature review, the addition of surfactants may have a negative impact on the thermal performance of the nanofluid; as such, the results collected are not skewed by the additional chemicals.

Figure 5.6: Comparison of samples

### 5.3.1 Comparison to numerical models

Of the numerical models presented in the literature review, only three will be used for comparative purposes, the Maxwell model, the Jeffery model and the Garoosi model. The modified Maxwell model was excluded due to the incorporation of the convective heat transfer. As the average size of nanoparticles produced at an industrial scale is 48 nm, this value will be used in the computation of the thermal conductivities of nanofluids (nanografi, n.d.). The diameter of a water molecule was found to be 2.8 angstrom which equates to 2.8 nm (D'Arrigo, 1978). The thermal conductivity of the nanoparticles was found to be 16.8 W/mK (Mariano *et al.*, 2015). **Table 5-6** shows the comparison of the recorded results to that of the numerical models. The Maxwell and Garoosi models severely over predict the thermal conductivity, whilst the Jeffery model closely approximates the value of sample A3 but not B3. The Maxwell model performance is to be expected as it assumes that the suspension is stable and does not account for the interfacial layer nor the low volume fraction. The Maxwell model is also the oldest model in use. The Garoosi model, based upon multiple data sets, attempts to fit a trend line to the results. All results consulted

for the Garoosi model had volume fractions less than 1%. The Garoosi model does not account for surfactants or the interactions between the base fluid and nanoparticles. The Jeffery model closely approximated sample A3 but could not do the same for sample B3. This is most likely due to the assumption that all particles are spherical in the model. It also does not account for the interactions between the base fluid and nanoparticle.

**Table 5-6: Comparison of test results to numerical models**

	Measured value	Maxwell model	Jeffery model	Garoosi model
<b>Sample A3</b>	0.255 W/mK	0.747 W/mK	0.262 W/mK	0.769 W/mK
<b>Sample B3 test 1</b>	0.454 W/mK	0.743 W/mK	0.258 W/mK	0.758 W/mK
<b>Sample B3 test 2</b>	0.467 W/mK			

It should be reiterated that the nanofluids tested had far higher volume fractions than most reported literature. Despite this, they yielded higher thermal conductivities but displayed lower stability.

### 5.3.2 Comparison to published literature

The measured results are compared to existing results for cobalt oxide nanofluid thermal conductivity. In comparison to results collected by Mariano *et al.*, they had found a mean thermal conductivity of 0.284 W/mK across volume fractions of 0.09% to 0.56% (Mariano *et al.*, 2015). The thermal conductivity of sample A3 was similar to those recorded with a deviation based upon the volume fraction. Sample B3, however, exhibited far higher thermal conductivities than those reported by Mariano *et al.* In fact, Alsoul *et al.* found thermal conductivities far higher than those recorded by the GHP, ranging from 0.260 W/mK to 0.296 W/mK. It should be noted that a KD 2 sensor was used, which is a Gustafsson probe. The volume fractions used ranged from 0.025 to 0.4% (Alsoul *et al.*, 2022). No surfactants were mentioned in the study. Based upon these comparisons, it is evident that sample A3 yielded similar results to those reported by these two groups who used ethylene glycol and cobalt oxide. Both studies did not make use of surfactants, so as such, the comparison is more valid as it proves the results obtained by the GHP. The higher-than-average thermal conductivity measured in sample B3 could be attributed to

agglomeration. It should again be reiterated that the volume fractions of the samples measured were far higher than those used in the studies for comparison.

## 6 CHAPTER SIX: Conclusion and recommendations

In conclusion, a GHP apparatus was designed and tested for the explicit purpose of testing fluids. The design relied primarily on the initial work of S. Choi and included modifications similar to that of Rausch. Due to the modular design, the apparatus is flexible and can be used for solids and liquids. It was noted that the device was susceptible to fluctuation in ambient conditions.

The GHP consisted of a core assembly, frame assembly and supporting electronics. The core was fabricated of two copper plates, A vesconite separation ring and two stainless steel retention plates. The fluid was held in the testing cavity by O-rings and two stainless steel M3 bolts. The frame assembly was constructed of stainless steel and aluminium. The core assembly was connected to the frame assembly using four nylon nuts and the bolt holes on the stainless steel retention rings. The supporting electronics were made into an embedded system designed around the Arduino nano microcontroller. An on-off controller and a PI controller controlled the guard heater and cold plate. An Agilent 34970A was used for data collection, and a GW instek GPS-3303 was used as the primary power supply to the heating cartridges.

Measurements were taken from the thermocouples placed through-out the hot and cold plates, the voltage drop across the heating cartridges and a current shunt placed across the wires connected to the heating cartridges to measure the power supplied.

The apparatus was calibrated using water and then used to test the thermal conductivity of a base fluid and then a nanofluid. From the tests, it appears that the device operates as intended. The device could accurately predict water and ethylene glycol thermal conductivity. Additionally, it was noted during the testing of the nanofluids that there was a distinct increase in the thermal conductivity of the base fluid through the addition of nanoparticles. Based upon the calibration, it was determined that there was a deviation of 2% from the reported literature; however, the ethylene glycol results were within 10% of the reported results.

In comparison to the performance of the testing devices used by Mariano *et al.* and Alsoul *et al.*, the GHP was capable of measuring within the range of the two despite the higher-than-typical volume fractions.

Furthermore, it was found that the addition of nanoparticles yielded a higher thermal conductivity. However, gravitational effects did take over and cause the nanofluids to become unstable. The instability resulted in errors in the readings and caused the nanoparticles to agglomerate.

## **6.1 Recommendations**

First and foremost, the cooling system should be replaced with a water-cooling loop maintained at the desired temperatures. This would alleviate the temperature fluctuations in the results because the PI controller only has a resolution of 0.25 °C. Furthermore, the guard heater should instead be relegated to an auxiliary guard heater, and a primary guard heater should then be designed in direct contact with the hot plate. Additionally, an environmental chamber capable of withstanding a vacuum should be incorporated into the design to alleviate the effects of ambient temperature fluctuations in the system. These aforementioned changes would minimise many of the losses found in the system.

Next, the control scheme should be redesigned to minimise noise and create an all-in-one system that does not rely on external power supplies or systems to function as intended. Other systems should also be incorporated into future builds to minimise the effects of handling the fluid sample; this could be done by incorporating a sonication system that would ensure the nanofluid sample is free of agglomeration. Additionally, the hot and cold plates could be coated in a thin film of diamond to prevent adverse reactions or interactions between the copper plates and the metallic particles in nanofluids. Additionally, an alternative material should be considered for the sample ring should higher testing temperatures be required for testing.

The present work has the potential for further exploration as the pressure transducer could be incorporated into the design, allowing for further insight into the nature of nanofluids and their properties.

## APPENDIX A: Calculations

### Assumptions:

$$m_h = 0.566 \text{ kg}$$

$$m_c = 0.266 \text{ kg}$$

$$\Delta T = 1 \text{ K}$$

$$C_p = 385 \text{ J/kg}\cdot\text{K}$$

$$Q = m_h * c_p * \Delta T$$

$$Q = 217.91 \text{ J}$$

$$Q = m_c * c_p * \Delta T$$

$$Q = 102.41 \text{ J}$$

Dimensions as per **Table 3-2: Stack assembly dimensions**

Hot plate analysis:

$$R_2 = \frac{L_2}{k_{copper} * A_2} = 0.001 \text{ K/W}$$

$$R_3 = \frac{L_3}{k_{copper} * A_3} = 0.006 \text{ K/W}$$

$$R_4 = \frac{L_4}{k_{vesconite} * A_4} = 10.341 \text{ K/W}$$

$$R_5 = \frac{L_5}{k_{copper} * A_5} = 0.003 \text{ K/W}$$

$$R_{parallel1} = \left( \frac{1}{R_3} + \frac{1}{R_4} + \frac{1}{R_5} \right)^{-1} = 0.002 \text{ K/W}$$

$$R_{hot \text{ plate}} = R_2 + R_{parallel1} = 0.003 \text{ K/W}$$

Testing area analysis:

$$R_6 = \frac{L_6}{k_{vesconite} * A_6} = 5.475 \text{ K/W}$$

$$R_7 = \frac{L_7}{k_{water} * A_7} = 7.194 \text{ K/W}$$

$$R_{parallel2} = \left( \frac{1}{R_6} + \frac{1}{R_7} \right)^{-1} = 7.194 \text{ K/W}$$

Cold plate analysis

$$R_8 = \frac{L_8}{k_{copper} * A_8} = 0.006 \text{ K/W}$$

$$R_9 = \frac{L_9}{k_{vesconite} * A_9} = 10.341 \text{ K/W}$$

$$R_{10} = \frac{L_{10}}{k_{copper} * A_{10}} = 0.003 \text{ K/W}$$

$$R_{11} = \frac{L_{11}}{k_{copper} * A_{11}} = 0.001 \frac{\text{K}}{\text{W}}$$

$$R_{parallel3} = \left( \frac{1}{R_8} + \frac{1}{R_9} + \frac{1}{R_{10}} \right)^{-1} = 0.002 \text{ K/W}$$

$$R_{cold \text{ plate}} = R_{11} + R_{parallel3} = 0.003 \text{ K/W}$$

Total:

$$R_{total} = R_{hot\ plate} + R_{parallel2} + R_{cold\ plate} = 3.115\ K/W$$

Power loss calculation:

$$P_{measured} = I.V = 1.065\ W$$

$$Q_{actual} = \frac{\Delta T}{R_{parallel2}} = 0.878\ W$$

$$Q_{lost} = P_{measured} - Q_{actual} = 0.175\ w$$

Therefore:

$$Cf = 1 - Q_{lost} = 0.825$$

Water thermal conductivity:

$$k_{water} = \frac{\Delta L}{R_w * Af} = 0.612\ W/mK$$

Glycol Thermal conductivity:

$$K_{sample} = \frac{V_1.V_2.C_f.\Delta L - \Delta T.R.K_v.A_1}{\Delta T.R.A_2} = 0.247\ W/mK$$

$$K_{sample} = \frac{V_1.V_2.C_f.\Delta L - \Delta T.R.K_v.A_1}{\Delta T.R.A_2} = 0.208\ W/mK$$

Sample A1 thermal conductivity test 1:

$$K_{sample} = \frac{V_1.V_2.C_f.\Delta L - \Delta T.R.K_v.A_1}{\Delta T.R.A_2} = 0.255\ W/mK$$

Sample B1 thermal conductivity test 1:

$$K_{sample} = \frac{V_1.V_2.C_f.\Delta L - \Delta T.R.K_v.A_1}{\Delta T.R.A_2} = 0.454\ W/mK$$

Sample B1 thermal conductivity test 2:

$$K_{sample} = \frac{V_1.V_2.C_f.\Delta L - \Delta T.R.K_v.A_1}{\Delta T.R.A_2} = 0.467\ W/mK$$

Numerical models:

Density of nanofluids:

$$\rho_{A3} = \left( (1 - \varphi_{A3}) \cdot \rho_f \right) + (\varphi_{A3} \cdot \rho_p) = 1.163 \times 10^3 \text{ kg/m}^3$$

$$\rho_{B3} = \left( (1 - \varphi_{B3}) \cdot \rho_f \right) + (\varphi_{B3} \cdot \rho_p) = 1.137 \times 10^3 \text{ kg/m}^3$$

Maxwell model:

$$k_{\text{sample}} = \frac{k_p + 2k_f + 2(k_p - k_f)}{k_p + 2k_f - (k_p - k_f)\varphi_{A3}} = 0.747 \text{ W/mK}$$

$$k_{\text{sample}} = \frac{k_p + 2k_f + 2(k_p - k_f)}{k_p + 2k_f - (k_p - k_f)\varphi_{B3}} = 0.743 \text{ W/mK}$$

Jeffery model.

$$k_e = k_f \left( 1 + 3\beta\varphi_{A3} + \varphi_{A3}^2 \left( 3\beta^2 + \frac{3\beta^2}{4} + \frac{9\beta^3}{16} \frac{\alpha + 2}{2\alpha + 3} + \frac{3\beta^4}{2^6} \right) \right) = 0.262 \text{ W/mK}$$

$$k_e = k_f \left( 1 + 3\beta\varphi_{B3} + \varphi_{B3}^2 \left( 3\beta^2 + \frac{3\beta^2}{4} + \frac{9\beta^3}{16} \frac{\alpha + 2}{2\alpha + 3} + \frac{3\beta^4}{2^6} \right) \right) = 0.258 \text{ W/mK}$$

Garoosi model:

$$\begin{aligned} k_e &= k_f \left( \frac{k_p + 2k_f + 2(k_p - k_f)\varphi}{k_p + 2k_f - (k_p - k_f)\omega\varphi} \right. \\ &\quad \left. + 3.762 \left( \frac{T}{T_0} \right)^{8.661} \left( \frac{d_p}{d_f} \right)^{-0.4351} \left( \frac{k_p}{k_f} \right)^{0.08235} \varphi^{0.64} e^{(-5.742\varphi)} \right) \\ &= 0.796 \text{ W/mK} \end{aligned}$$

$$\begin{aligned} k_e &= k_f \left( \frac{k_p + 2k_f + 2(k_p - k_f)\varphi}{k_p + 2k_f - (k_p - k_f)\omega\varphi} \right. \\ &\quad \left. + 3.762 \left( \frac{T}{T_0} \right)^{8.661} \left( \frac{d_p}{d_f} \right)^{-0.4351} \left( \frac{k_p}{k_f} \right)^{0.08235} \varphi^{0.64} e^{(-5.742\varphi)} \right) \\ &= 0.758 \text{ W/mK} \end{aligned}$$

## Vesconite - Typical Properties

		METRIC	IMPERIAL
Density (Specific Gravity)		1.38	1.38
Melting point		260°C	500°F
Hardness - Shore D (ASTM D2240)		83	83
Compressive Properties (ASTM D695 - 15)	Compressive Strength @ Yield	93 MPa	13,489 psi
	Modulus of Elasticity	2.3 GPa	333,590 psi
Tensile Properties (ASTM D695 - 15)	Tensile Strength @ Yield	66 MPa	9,573 psi
	Tensile Strength @ Break	63 MPa	9,137 psi
Tangent modulus of elasticity (ASTM D-790)		3,726 MPa	540,410 psi
Water swell - Mass change (ASTM D570)	After 24 hours		0.11%
	After 28 days		0.12%
Oil swell - Mass change (ASTM D570)	After 24 hours		0.077%
	After 28 days		0.092%
Shear strength (ASTM D732 -17)		49.1MPa	7,121 psi
Flexural yield strength		120 MPa	17,400 psi
Deflection temperature at 1.85MPa / 268 psi		93°C	200°F
Notched impact strength - Charpy (ISO 179)		245 kJ/m <sup>2</sup>	0.49 ft-lb/in <sup>2</sup>
Notched impact strength IZOD		30 J/m	0.56 ft-lb/in
Heat conductivity		0.3 w/m.K	2 Btu-in/ft <sup>2</sup> .hr.°F
Coefficient of linear thermal expansion		6x10 <sup>-5</sup> mm/mm.°C	3.3x10 <sup>-5</sup> in/in.°F
Dynamic friction coefficient on polished steel (no lubrication)		0.13 - 0.18	0.13 - 0.18
Dielectric strength		14kV/mm	360kV/in
Gamma ray resistance 50% loss of properties		100 Mrads	100 Mrads
The above data should be taken for indicative purposes. Physical properties may be altered to some extent by processing conditions.
